SUBJECT INDEX

A-level and the Schools Council, news, 1260
Abdominal Ganglion of Aplysia californica, Possible Neuroendocrine Function of Bag Cells of, Stimulation of Egg Laying: (Irving Kupfermann), 814
Abiogenesis from Pyrrole and Formaldehyde under Simulated Geochemical Conditions, Porphyrin (G. W. Hodgson and B. L. Baker), 29
Abnormalities, Sex Chromosome (Richard M. Goodman, William S. Smith, and Clause J. Migeon), 92
Abortion in Mice by Heterologous Immune Serum, Inhibition of Egg Implantation and Induction of (D. R. S. Kirby), 1220
Abscission induced by Betahydroxyethyl-hydrazine: Conversion of Betahydroxyethyl-hydrazine to Ethylene (R. L. Palmer, L. N. Lewis, H. Z. Hield and J. Kumamoto), 1216
Absence of Testosterone in Urine of Rats (Guillemo F., Carrera, Roy L. Ponthier, jun., and Bernard F. Rice), 1128
Absolute Configuration and the Structure of Chlorophyll (lan Fleming), 151;
Experimental and Theoretical Determination of the Copper-63 (n,2n)Copper-62 Reaction Cross-section (A. J. Cox and D. Crumpton), 996
Absorption Lines in Quasi-stellar Objects (G. R. Burbidge and E. M. Burbidge), Fixing Extracts of Clostridium pasteurianum: (Esam Moustafa and L. E. Mortenson), 1241

Adrenergic Transmission in Small Arteries (R. N. Speden), 289

Adsorption of Wetting Agents and Detergents at "Graphon" Solution Interface, Rates of (A. C. Zettlemoyer, V. V. Suba Rao and Robert J. Fix), 683;

on Silica Gel. Lason Raman Spectra of Socked Species Physical (R. L. Adsorption of Wetting Agents and Detergents at "Graphon" Solution Interface, Rates of (A. C. Zettlemoyer, V. V. Suba Rao and Robert J. Fix), 683; on Silica Gel, Laser Raman Spectra of Sorbed Species Physical (P. J. Hendra and E. J. Loader), 789
Advanced Theory of Statistics, The Vol. 3: Design (Maurice G. Kendall and Alan Stuart), review by D. J. Finney, 727
Advances in Chromatography, Vol. 4 (edited by J. Calvin Giddings and Roy A. Keller), review by R. Consden, 1252; in Computers, Vol. 8 (Franz L. Alt and Morris Rubinoff), review by M. V. Wilkes, 901; in Heterocyclic Chemistry (edited by A. R. Katritzky and A. J. Boulton), Vols. 7 and 8, review by G. L. Buchanan, 520; in Immunology (edited by F. J. Dixon, jun., and J. H. Humphrey), Vol. 6, review by R. R. Porter, 411; in Reproductive Physiology (edited by Anne McLaren), review by T. D. Glover, 1148; in Teratology, Vol. 2 (edited by D. H. M. Woollam), review by J. D. Boyd, 1248
AEA, future, Select Committee report, news, 735, 838
Aegilops cylindrica, Confirmation of the Genome Donors of (B. L. Johnson), 859
AEI-GEC merger, news, 630
Ag(2) Factor, Study of the (A. Vierucci, B. S. Blumberg and G. Morganti), 1231
Agar by Gamma Irradiation, Stable (Y. A. Doshi and P. S. Rao), 931
Age and Diet in the Metabolism of 7.12-Dimethylben[a]-anthracene by Rat Liver Homogenates, Variations dependent on (P. Sims and P. J. Grover), 77; of the Paresis Complex, South-West Africa (W. I. Manton and G. Siedner), 1197; on the Amino-acids associated with Vascular Heparan and Chondroitin Sulphates, Effect of (G. Manley and R. N. Mullinger), 603
Aggilutination between Established Burkitt Cell Lines and Fresh Biopsy Specimens, Mixed (Richard T. Smith, George Klein, Eva Klein, and Peter Clifford), 693
Agglutination between Established Burkitt Cell Lines and Fresh Biopsy Specimens, Mixed (Richard T. Smith, George Klein, Eva Klein, and Peter Clifford), 693
Agglutinins, Cold: Search for Antigen I in Human Tissues (Ten Feizi and Elizabeth Monger), 1025
Aggragation of Sub-units to produce Mu Absorption Lines in Quasi-stellar Objects (G. R. Burbidge and E. M. Burbidge), 1092; Absorption Lines in Quasi-stellar Objects (G. R. Burbidge and E. M. Burbidge), 1092;
Role of Intestinal Lymphatics in Copper (Irmin Sternleib, Cornelis J. A. Van Den Hamer and Seymour Alpert), 824
Abstract Algebra (Andrew O. Lindstrum), review by H. O. Foulkes, 727; usefulness, news, 737
Acacia georginae and Some Other Plants, Observations on the Metabolism of Fluoride in (Rudolph A. Peters and M. Shorthouse), 80
Accelerator, CERN, delayed, news, 1156;
new 300 GeV proton, CERN, news, 215, 316;
Radiation Use of Ethylene as a Gas Phase Dosimeter for (A. R. Anderson and J. V. F. Best), 576
Accelerators: Superconducting Magnets in High Energy Physics (P. F. Smith and D. B. Thomas), 964
Accumulation of Nitrite in Fresh Soils after Gamma Irradiation (P. A. Cawse and D. V. Crawford), 1142
Acetyl-CoA Pathways in Two Nervous Tissues, Relative Contribution of Carbon Dioxide Fixation and (Sze-Chuh Cheng, Rikuro Nakamura and Heinrich Waelsch), 928
Acetylacetonate in Benzene Solution, Electrical Polarization and Microwave Absorption of Aluminium (E. N. DiCarlo and R. E. Stronski), 679
Acetylcholinesterase by Debenamine, Irreversible Inhibition of (F. Beddoe and H. J. Smith), 706
Acetylene Reduction by Nitrogen Fixing Extracts of Clostridium posteruidnum: ATP Requirement and Inhibition by ADP (Esam Moustafa and L. E. Mortenson), 1241
Acherknecht, Arwin H.: Medicine at the Paris Hospital, review, by Edwin Clarke, 1251
Achondrites, Plutonium-244 in the Early Solar System and Concordant Plutonium/Xenon and lodin/Xenon Decay Intervals of (D. D. Sabu and P. K. Kuroda), 442
Acid Conversions of Hydrazoarenes (D. V. Banthorpe, Anthony Cooper and C. K. Ingold), 232;
Phosphatase Isozymes in the Synovial Fluid of Patients with Rheumatoid Arthritis, Appearance of Specific (L. Beckman, G. Beckman and R. Lemperg), 274
Acidity in Human Eccrine Sweat, Ammonia and the Regulation of (Taketoshi Morimoto and Robert E. Johnson), 813
Acoustic Waves, Ionospheric Irregularities caused by (D. B. Rai and J. L. Kisabeth), 568
Acquired Radioresistance Air Bubbles studied by the Time Exposure Technique, Bursting (J. A. Day), 1097

Air pollution: Diesel Exhaust Particulates (J. W. Frey and M. Corn), 616
Aircraft from US, parliamentary news, 1265
Airlines, slower progress, news, 111
Albumin, Binding of Cortisol to Human (Jean Pearson, P. M. Keane and W. H. C. Walker), 1335:
Polymorphism in North American Indians, Serum (H. F. Polesky and D. A. Rokala), 185
Alcohol, Influence of Acute and Chronic Administration of, on Carbohydrate Breakdown and Energy Metabolism in the Liver (H. P. T. Ammon and C. J. Estler), 158
Aldabra, conflicting statements, news, 841;
expedition, news, 5;
no plans for conservation, news, 846;
Royal Society action, news, 633
Aldolase, quaternary structure, news, 117
Aleutian Disease Gammopathy of Mink induced with an Ultra-filtrable Agent (L. Buko and A. J. Kenyon), 69
Alexander, R. McN.: Functional Design in Fishes, review by James C. Chubb, 1250
Alga Fritschielle, Green, Cytokinesis in the (Gordon E. McBride), 939 Kisabeth), 568

Acquired Radioresistance of Tumour Cells (S. B. Balmukhanov, M. L. Yefimov and T. S. Kleinbock), 709

Actinomycin Blockage of RNA Synthesis, Microsomal Protein Synthesis in the Isolated Perfused Liver during (J. G. Nievel and W. Dawson), 818; Don the Susceptibility of Nicotion glutinosa L. to infection by Tobacco Mosaic Virus, Effects of Kinetin and (A. K. Mukherjee, L. C. Soans and M. Chessin), 1344

Action of Cytochalasin B on Cultured Human Lymphocytes (G. F. Smith, M. A. C. Ridler and Janet A. Faunch), 1134

Actions of Thrombin and Other Coagulant and Proteolytic Enzymes on Blood Platelets (M. G. Davey and E. F. Lüscher), 857

Activation of Glucose-6-phosphatase of Rat Liver at High pH: Differential Response of Basal and Induced Activities (P. N. Pandhi and H. Baum), 1324

Acyrthosiphon, pisum Harris, Role of Host Plant in Production of Winged Forms Alga Fritschiella, Green, Cytokinesis in the (Gordon E. McBride), 939
Algae, Uncoating and Development of Vaccinia Virus in Miniature Cells induced with an Extract from Marine (T. J. Starr and O. A. Holtermann), 600
Algal toxins, news, 851
Algebraic Model of the Lactation Curve in Cattle (P. D. P. Wood), 164
Alginate to the Diet, Reduction of Strontium Absorption in Man by the Addition of (Alice Sutton), 1005
Alignment, Correction for Atmospheric Refraction in Surveying and (J. Dyson), 782
Alkali, Semiruingen, Mosel Survey. Response of Basal and Induced Activities (P. N. Pandhi and H. Baum), 1324

Acyrthosiphon pisum Harris, Role of Host Plant in Production of Winged Forms by a Green Strain of Pea Aphid (O. R. W. Sutherland), 387

Added Solutes on the Size of Hydrogen Bubbles liberated from a Cathode Wire in Aqueous Solution, Effect of (M. J. Blandamer, F. Franks, K. H. Haywood and A. C. Tory), 783

Additive Butylated Hydroxytoluene on Monolayer Cultures of Primate Cells, Effects of the Food (Susan M. Milner), 557

Additives for food, parliamentary news, 958

Adenosine Diphosphate on Adhesiveness of Platelets in vitro and in vivo, Effect of X (Manabu Yamanaka, Junichi Isobe and Yasuta Kono), 175

Adenovirus-Type 3, Transformation of Primary Rat Embryo Cells by a Weakyl Ocogenic (A. E. Freeman, E. A. Vanderpool, P. H. Black, H. C. Tirmer and R. J. Huebner), 171

Adenoviruses for Mammalian Cells, Mutagenic Capacity of (H. F. Stich and D. S. Vohn), 1292

Adesmacea: Shell Movements of a Wood Boring Bivalve (Alan D. Ansell and N. Balakrishnan Nair), 595

Adhesiveness of Platelets in vitro and in vivo, Effect of Adenosine Diphosphate on (Manabu Yamanka, Junichi Isobe and Yasuta Kono), 175

ADP, ATP Requirement and Infibition by: Acetylene Reduction by Nitrogen

Alkali, Semiquinone-, Metal Systems, Origin of Linewidth Alternation in (T. A. Claxton, I. Oakes and M. C. R. Symons), 914

Alkaline Phosphatase Relationships in Drosophila (Herbert Schneiderman), 604

Alkaloids, An Introduction to the (G. A. Swann), review by D. H. G. Grout, 620

Alkyl Metal Compounds, Tetra, Total Ionization Cross-section of some (J. J. de Ridder and G. Dijkstra), 260

Allcock, H. R.: Heteroatom Ring Systems and Polymers, review by C. E. H. Bawn, 619

Alleles at a Restricted Sublocus of Dumpy in Drosophilia melanogaster, Rare Pseudoallelic Crossover between Two Phenotypically Identical (Ronald Sederoff), 1348

Allergic Encephalomyelitis in Mice by Irradiation of the Target Organ, Suppression of Experimental (Labe C. Scheinberg, Johanna M. Lee and Judith M. Taylor), 924

Allison, Anthony (editor): Penguin Science Survey: The Biology of Sax, review Allison, Anthony (editor): Penguin Science Survey: The Biology of Sax, review by Ursula Mittwoch, 203

INDEX

(Alium sativum), Induction of Tumour Immunity with Tumour Cells treated with Extract of Garlic (Motonori Fujiwara and Toshikazu Natata), 83

Alloys, Irradiation Creep in Several Metals and, at 100°C (G. W. Lewthwaite, D. Mosedale and I. R. Ward), 472;
strength of ordered, news, 538

Alloxan Diabetes, Starvation and Refeeding on Glycolytic Kinase Activities in Rat Epididymal Adipose Tissue, Effect of (C. I. Pogson and R. M. Denton), 156:

in Rat Epididymal Adipose Tissue, Effect of (C. I. Pogson and R. M. Denton), 156;
Protection of Canine Pancreatic Ultra-structure against Radiation Damage by Post-treatment with (Klaus F. Weilmann, Bruno W. Volk and Sydney S. Lazarus), 86

Alloys, Oxidation of Iron-Chromium Binary (P. K. Footner, D. R. Holmes and D. Mortimer), 54;
Permanent Magnet Properties of Platinum-Cobalt (R. A. McCurrie), 149;
The Tabasalanus of Hanny New Footney Mostels and U. H. Cainn and

Damage by Post-treatment with (Klaus F. Wellmann, Bruno W. Volk and Sydny S. Lazarau), 86

Alloys, Oxidation of tron-Chromium Binary (P. K. Footner, D. R. Holmes and D. Mortimer), 54;

Permanent Magnes Properties of Platinum-Cobalt (R. A. McCurrie), 47;

Arsenicals and Antimonials, a Selective Antagonism of (N. Ercoli), 398
Arterial Oxygen on Mammalian Brain Oxygen Tension, Effect of (Carl R. Merril, C. Charlton, P. Yarnell and A. K. Ommaya), 295
Arteries, Adenergic Transmission in Small (R. N. Speden), 289
Arthritis, Appearance of Specific Acid Phosphatase Isozymes in the Synovial Fluid of Patients with Rheumatoid (L. Beckman, G. Beckman and R. Lemperg), 274

riuid of Patients with Rheumatoid (L. Beckman, G. Beckman and R. Lemperg), 274

Artichoke: Rapid Isolation of Active Mitochondria from Plant Tissue (J. M. Palmer), 1208

Artificial Feeding Technique for Rhipicephalus appendiculatus and the Transmission of Theileria parva from the Salivary Secretion (R. E. Purnell and L. P. Joyner), 484

INDEX xvi

Bactericidal factors: Bacterial Inhibitors in Milk and other Biological Fluids
(B. Reiter and J. D. Oram), 328
Bacteriophage RNA, GTP-Stimulated Binding of Initiator-tRNA to Ribosomes directed by f2 (John A. Anderson, James E. Dahlberg, Mark S. Bretscher, Michel Revel and Brian F. C. Clark), 1072
Bacteriostatic factors: Bacterial Inhibitors in Milk and other Biological Fluids
(B. Reiter and J. D. Oram), 328
Baddiley, Professor J., Royal Society Lecture, news, 636
Bag Cells of Abdominal Ganglion of Aplysia californica, Possible Neuroendocrine Function of, Stimulation of Egg Laying: (Irving Kupfermann), 814
Baker, D. B.: Design of Active-Site-Directed Irreversible Enzyme Inhibitors, review by K. Dalziel, 1356
Balanced Synthesis of Light and Heavy Chains of Immunoglobulin G (Brigitte A. Askonas and Alan R. Williamson), 264
Banded Flints (J. Jocelyn), 781
Bands, Lattice, in Interstellar Grains, Evidence for (N. C. Wickramasinghe), 249
Barlum Methacrylate Dihydrate under X-radiation, Structural Changes of (N. W. Isaacs, C. H. L. Kennard and J. H. O'Donnell), 1104
Barnacle: Possible Mechanism for the Endocrine Control of Breeding in a Cirripede (D. J. Tighe-Ford), 920
Barnes, Harold (editor): Oceanography and Marine Biology, Annual Review, Vol. 4, review by Derek Dorsett, 894
Barley Embryos, Gibberellin from (Anna M. McLeod and G. H. Palmer), 1342; Roots, Conflicting Measurements of Sodium and Potassium Uptake by (M. G. Pitman), 1343
Barnyard Grass, Ensyme Detoxication of 3', 4'-Dichloropropionanilide in Rice and, a Factor in Herbicide Selectivity (C. C. Still and O. Kuzirian), 799
Barrett, E. C.: Viewing Weather from Space, review by P. Larsson, 1355
Barron Mays, John: Crime and the Social Structure, review by W. H. Scott, 310
Basal and Induced Activities, Differential Response of, Activation of Glucose-6-phosphatase of Rat Liver at High pH: (P. N. Pandhi and H. Baum), 1324 Arts v. Science, Essays (edited by Alan S. C. Ross), review by A. D. C. Peterson, 822

Arvill, Robert; Man and Environment, review by B. E. Juniper, 1049

Ascites, BPB, (Sarcoma) Tumours on Glycolipid Composition in Kidneys of Mice, Effect of (E. P. Adams and G. M. Gray), 277

Ashmore, P. G., Dainton, F. S., and Sugden, T. M. (editors): Photochemistry and Reaction Kinetics, review by James C. Robb, 410

Asians, Lactose intolerance in (A. E. Davis and T. Bolin), 1244

Aspartic Acid, Thermal Poly-α-amino-acids containing Low Proportions of (Duane L. Rohlfing), 657

Aspects of Marine Zoology (Symposium), review by Derek A. Dorsett, 99

Aspergillus niger, Degradation of Salicylate by (Lawrence R. Krupka, Fred A. Racle and Ara Der Marderosian), 487;

Twin Spots as Evidence for Mitotic Crossing-over induced by Ultraviolet Light in (Stephen Wood and Etta Käfer), 63

Asteroid, Icarus, near collision, news, 529

Astrobleme, Shatter Cone Orientation at Gosses Bluff (Robert S. Dietz), 1082

Astronomy at Cambridge, Theoretical (F. L. Westwater), news, 432;

in Britain, news, 848

Astrophysics at Culham, SRC unit, news, 1061

Atherosclerosis, Tea and (Wei Young, Robert L. Hotovec and Arthur G. Romero), 1015

Atlantic Ocean, North, and its Margins, Early History of (W. B. Harland), 464;

South-central North, Late Pliocene-Pleistocene Stratigraphy in Deep Sea Cores from the (W. A. Berggren, J. D. Phillips, A. Bertels and D. Wall), 253

Atmospheric Electricity, Current Density Measurements in (P. M. Buis), 360;

Model, Interhemispheric Transfer of Debris from Nuclear Explosions using a Simple (D. H. Peirson and R. S. Cambray), 755; Arts v. Science, Essays (edited by Alan S. C. Ross), review by A. D. C. Peterson, Basal and Induced Activities, Differential Response of, Activation of Glucose-6-phosphatase of Rat Liver at High pH: (P. N. Pandhi and H. Baum), 1324
Basement Membrane, Molecular Sieving by Glomerular (Flora Huang, Linda Hutton and Norman Kalant), 87
Basic Astronomy (Patrick Moore), review by Peter Sykes, 1353
Basis of Modern Physics, The (J. M. Irvine), review by Peter Sykes, 1353
Bats, Fruit, in Thailand, Isolation of Rabies Virus from (Paul C. Smith, Kwan-yuen Lawhaswasdi, William E. Vick and J. S. Stanton), 384;
Longevity of Thinolophid, in Britain (John H. D. Hooper and Winifred M. Hooper), 1135
Batyl Alcohol, Protective Effects of, Anaemia, Thrombocytopenia and Reduced Platelet Adhesiveness in Rats fed Bracken Fern, and (R. B. Philp and C. W. Gowdey), 498
Bazill, G. W.: Lethal Unbalanced Growth in Bacteria, 346
BEA, inquiry, news, 630 Model, Interhemispheric Transfer of Debris from Nuclear Explosions using a Simple (D. H. Peirson and R. S. Cambray), 755;
Refraction in Surveying and Alignment, Correction for (J. Dyson), Refraction in Surveying and Alignment, Correction for (J. Dyson), 782.

Atomic Energy Authority, annual report, news, 108.

At you Mitochondria, Involvement of a Membrane Potential in the Synthesis of (I. M. Glynn), 1316;

Inorganic Pyrophosphate and, as Energy Donors in Chromatophores from Rhodospirillum rubrum (Margareta Baltscheffsky), 241;

Requirement and Inhibition by ADP, Acetylene Reduction by Nitrogen Fixing Extracts of Clostridium posteurianum: (Esam Moustafa and L. E. Mortenson), 1241

ATP: Specific Binding of Sodium and Potassium Ion in Erythrocyte Membranes (B. Z. Ginzburg, T. Friedlander and E. Pouchovsky,) 1185

ATPase Activity at the Functional Contacts between Retinal Cells which produce S-potential (J. A. O'Daly), 1329

Attachment of Rapidly Labelled RNA to Polysomes in the Absence of Ribosomal RNA Synthesis during Normal Cell Differentiation (J. B. Gurdon and P. J. Ford), 666

Attenuation, Ultrasonic, in the Pre-melting Region (G. A. Saunders, N. G. Page and T. Alperl, 1298

Attitude Determination of the Ariel III Satellite (R. M. Brent), 45

Attraction and Repulsion (Malcolm McCraig), review by Peter Sykes, 1353

A typical Menaquinone Pattern in a Strain of Staphylococcus aureus (L. Jeffries, Margaret Harris and S. A. Price), 808

Aurora, Infrasonic Pressure Waves from: a Shock Wave Model (Charles R. Wilson), 131

Australia during 1965, Concentrations of Beryllium-7 over (B. B. Hicks), 250

Australian fisheries, news, 426;

Iron Meteorites, Differences of Composition among (John T. Wasson), 880

Autommunity: Clinical and Experimental (J. R. Anderson, W. W. Buchanan Platelet Adhesiveness in Rats fed Bracken Fern, and (R. B. Philp and C. W. Gowdey), 498
Baxill, G. W.: Lethal Unbalanced Growth in Bacteria, 346
BEA, inquiry, news, 630
Beagle Dog Plasma, Factor VII Deficiency in, and its Use in the Assay of Human Factor VII (R. Garner, C. Hermoso-Perez and D. M. Conning), 1130
Beating the Balance of Payments with new industries, news, 108
Beef Production from Molasses and Urea, Intensive (T. R. Preston, A. Elias, M. B. Willis and T. M. Sutherland), 721
Beer, Albert C.: see under Willardson, R. K.
Behaviour Change induced by Mescaline, Alterations by Pretreatment with Iproniazid and an Inactive Mescaline Analogue of a (J. R. Smythies, V. S. Johnston and R. J. Bradley), 196;

-disrupting Amphetamines, Some New, and their Significance (J. R. Smythies, V. S. Johnston, R. J. Bradley, F. Bennington, R. D. Morin and L. C. Clark, jun.), 128;

in the Rat of Visual Pattern Restriction in Early Life, Effect on Brain Enzyme and (Devendra Singh, Richard J. Johnston and Harold J. Klosterman), 1337

Behavioural Sciences, Zoology and (W. H. Thorpe), 17
Behr, Lyell, Fusco, Rafaello, and Jarboe, C. H.: Pyrazoles, Pyrazolines, Pyrazolidines, Indazoles and Condensed Rings, review by W. J. Barry, 1252
Bence-Jones Proteins, Distribution of an Arginine-Lysine Interchange in the Invariable Half of Human L-Type (R. Quattrocchi, D. Cioli and C. Baglioni), 56

Benzene Solution, Electrical Polarization and Microwave Absorption of Aluminium Acetylacetonate in (E. N. Dicarlo and R. E. Stronski), 679
Benzidine Rearrangements: Acid Conversions of Hydrazoarenes (D. V. Banthony, Cooper and C. K. Ingold), 232

Berg, Paul W., and McGregor, James L.: Elementary Partial Differential Equations, review by R. L. Perry, 307

Bernfeld, Marvin: see under Cook, Charles E. Berthe, Professor Hans, Nobel Prize, news, 424

Beryllium-7 over Australia during 1965, Concentrations of (B. B. Hicks), 250

Betahydroxyethylhydrazine, Abscission induced by: Conversion of Betahydroxyethylhydrazine to Ethylene (R. L. Palmer, L. N. Lewi Iron Meteorites, Differences of Composition among (John T. Wasson), 880

Autoimmunity: Clinical and Experimental (J. R. Anderson, W. W. Buchanan and R. B., Goudie), review by J. E. Fothergill, 831

Automation (J. Rose), review by Peter Sykes, 1353

Autoration (J. Rose), review by Peter Sykes, 1353

Autoratiogram, Size Relation between a Chromatrographic Spot and its (S. Aronoff and Otto Suschny), 1214

Autoradiographic Detection of Reactive Protein-SH and its application to Anuran Haemoglobin Chains (Lewis P. Stratton and Earl Frieden), 932;

Study of the Effects of Cortison on DNA Synthesis in Lymphatic 932;
Study of the Effects of Cortison on DNA Synthesis in Lymphatic Tissue (Robert F. Lang, Walter Stevens and Thomas F. Dougherty), 934
Autoradiography and Biochemistry, Quantative Evaluation of Tritium in (S. R. Pelc and M. G. E. Welton), 925
Autotropic metabolism, news, 1267
Auxin-dependent Tumours, Successful Tissue Transplantation and some of its Problems (Denes De Torok), 376
Avena Coleoptile by Xylamidine Tosylate, Antagonism of Tryptamine Stimulated Growth in Apices of (Alan Winter), 801
Axial Organ of Arbacia punctulata and its Implications, Regeneration of the (N. Millott and A. Farmanfarmaian), 1136
Axoplasmic Components, Bidirectional Transport of Radioactively Labelled (Raymond J. Lasek), 1212 Binary Alloys, Oxidation of Iron-Chromium (P. K. Footner, D. R. Holmes and and D. Mortimer), 54

Binding Capacity of Histamine related to the Supply of Histamine (T. H. Lippert), 1226;
of Cortisol to Human Albumin (Jean Pearson, P. M. Keane and W. H. C. Walker), 1335

Binocular Vision in Cats, news, 1067

Binuclear Carbonato-complex of Chromium (11) (R. D. Cannon and J. L. Tsay), 681

Bioassay of Captan by Zebrafish Larvae (Z. H. Abedi and W. P. McKinley), 1321

Biochemical Alteration to Antifolate Resistance in L 1210 Leukaemia, Sequential (F. M. Sirotnak, S. Kurita, M. Gay Sargent, D. L. Robinson and Dorris J. Hutchison), 1236

Biochemistry of Blood Platelets (Colloquium), review by R. M. Hardisty, 724

Biogenesis, future of? news, 635

Biological Form, Numerical Specification of (B. Meltzer, N. H. Searle and R. Brown), 32;
Materials, Electron Paramagnetic Resonance in Frozen and Dried (R. J. Heckly and R. L. Dimmick), 1003;
Systems, Reactivity of Trapped Free Radicals in (W. F. Forbes, and J. V. Ramsbottom), 913

Biology, Institute of, conference, news, 957;
of Fungi, Bacteria and Viruses, The (Greta Stevenson), review by J. R. S. Fincham, 521;
Programme, International, in US, news, 842

Biopolymers by Differential Thermal Analysis, Denaturing Kinetics of (Horst W. Hoyer), 997

Biosynthesis of Glyceride, Stimulation of (G. Hübscher, D. N. Brindley, M. E. Smith and B. Sedgwick), 449

Biosynthetic Functions, Study of Microbial Evolution through Loss of: Establishment of "Defective" Mutants (Stephen Zamenhof and Herbert H. Eichhorn), 456;

Bacteria and Plastics meeting, news, 539;
and Viruses, The Biology of Fungi, (Greta Stevenson), review by J. R. S. Fincham, 521;
-free Culture of Oyster Larvae (R. H. Millar and J. M. Scott), 1139;
isolated from Rivers of the Amazon Region, Oxidation of Sulphonic Compounds by Aquatic (Hebe L. Martelli), 1238;
Lethal Unbalanced Growth in (G. W. Bazill), 346;
New Type of Restriction to the Expression of a Structural Gene in (M. H. Richmond), 1191;
Selective Feeding of Turbificids on (R. A. Coler, H. B. Gunner and B. M. Zuckerman), 1143;
Soil, to High Temperatures and Diurnal Freezing and Thawing, Response of (R. S. Young, P. H. Deal and O. Whifield), 355
Bacterial Agent from Rabbit Polymorphonuclear Leucocytes, Leukin, a (Robert C. Skarnes), 806;
cell walls, Royal Society Lecture, news, 636;
Infections, Severe, Abnormal Distribution of Haemoglobin Genotypes in Negro Children with (R. Eeckels, F. Gatti and A. M. Renoirte), 382;
Inhibitors in Milk and other Biological Fluids (B. Reiter and J. D. Oram), 382;
Photosynthesis. Integration of Energy Conversion and Biosynthetic

382;
Photosynthesis, Integration of Energy Conversion and Biosynthetic Processes in (Gary A. Sojka, George A. Din and Howard Gest), 1020;
Spores, Sorption of Water Vapour and Nitrogen Gas by (Rex Neihof, J. K. Thompson and V. R. Deitz), 1304;

Eichhorn), 456;

Processes in Bacterial Photosynthesis, Integration of Energy Conversion and (Gary A. Sojka, George A. Din and Howard Gest), 1020

Birds, Non-thermal Effects of Microwave Radiation on (J. A. Tanner, C. Romero-Sierra and S. J. Davie), 1139

Birefringence in Unfixed Lemon Fruit Nucleoli (H. A. Kordan and R. D. Preston), 1105

Bis-1,2-dithiolenes, Lewis Base Adducts of Cobalt and Iron (N. G. Connelly, J. A. McCleverty and C. J. Winscom), 999

BISRA, news, 320

Bissell, Harold J.: see under Chilingar, George V.

Bitter, Professor Francis, obituary by George R. Harrison, 1253

Bitterbrush (Purshia tridentata (Pursh) D.C.), Fixation of Nitrogen by (S. R. Webster, C. T. Youngberg and A. G. Wollum II), 392

Bittner Virus, Lack of Resistance of Adult Mice to Erythrocyte-bourne (S. Nandi), 809

Bivalve, Shell Movements of a Wood Boring (Alan D. Ansell and N. Balakrishnan Nair), 595

Blackbody Radiation and the Eddington-Lemaître Universe (R. C. Roeder and R. H. Chambers), 774

Blackett on 300 GeV machine, news, 841

Blackwelder, R. E.: Taxonomy, review by J. E. Webb, 895

Bladder and Kidney, Toad, Significance of Respiratory Quotients in (Julius J. Cohen), 399

Blasts in Human Acute Leukaemia, Non-self-maintaining Kinetics of Proliferating (F. Gavosto, A. Pileri, V. Gabutti and P. Masera), 188

Blebs, Nuclear: Nuclear Pockets in Normal Monocytes (D. Huhn), 1240

Blindness research, news, 535

Blood Clots, Factors influencing Lysis of Whole (Fletcher B. Taylor and Hans J. Müller-Eberhard), 1023;

Clotting Enzymology (edited by Walter H. Seegers), review by M. P. Esnouf, 411;

Group Studies of the "Gene Bank" Sheep at Whipsnade Park (Elizabeth M. Tucker), 684;

Group Studies of the "Gene Bank" Sheep at Whipsnade Park (Elizabeth M. Tucker), 684;

Groups in Natives of Easter Island (R. Etcheverry), 690;

Meals service, establishment, news, 1163;

Platelets, Actions of Thrombin and Other Coagulant and Proteolytic Enzymes on M. G. Davey and E. F. Lüscher), 857;

Platelets, Biochemistry of (Colloquium), review by R. M. Hardisty, 724:
Platelets, Subcellular Localization of 5-Hydroxytryptamine and Histamine in (M. da Prada, A. Pletscher, J. P. Tranzer and H. Knuchel), Histamine in (M. da Prada, A. Pletscher, J. P. Tranzer and H. Knuchel), 1315;
Simulted: Erythrocyte Substitute for Perfusion of Brain (Henry A. Sloyiver and Toshiharu Kamimoto), 458;
Yield Stress, Static Method for determining (S. E. Charm and G. S. Kurland), 1/21;
Blowfly, Australian sheep: "Booby-trapping" as an Alternative to Sterile, Males for Insect Control (M. J. Whitten and K. R. Norris), 1/36
BO,; Emission from Injection of Triethlyborane into the Upper Atmosphere (R. C. Millikan), 571
Boas, Franz: Kwakiutl Ethnography, review by Audrey Butt, 884
Boerma, Dr. A. H., director-general of FAO, news, 736
Body Burdens of Caesium-137 in Toronto in 1964-1967 (K. G. McNeill and Joan E. Harrison), 1340;
Fluids and Their Function, The (Garth Chapman), review by P. J. Kelly, 1251;
Temperature, Release of Brain Serotonin and (M. H. Sheard and G. K. Aghajanian), 495
Bombyx mori L., Accumulation of Glycine in the Fat Body of the Silkworm, (C. Chitra and M. B. Shyamala), 386;
Establishment of a Line of Cells from the Silkworm (T. D. C. Grace), 613

(C. Chirra and M. B. Shyamala), 386;
 Establishment of a Line of Cells from the Silkworm (T. D. C. Grace), 613

Bond Formation from Methylene Chloride over Evaporated Titanium Films, Catalytic Carbon-Carbon (J. R. Anderson and B. H. McConkey), 681

Bondling between Proteins and Lipids in the Envelopes of Halobacterium halobium (C. W. F. McClare), 767;
 Radii of 80S Ribosomes (R. S. Morgan and F. D. Kellogg), 1302

Bonds, Single, in Simple Molecules, Role of Van der Waals Interaction on Hindered Rotation about (J. L. DeCoen, G. Elefante, A. M. Liquori and A. Damiani), 910

Bone in Organ Culture, Determination of Growth Inhibitory Concentrations of Tetracycline for (Ian C. Bennett, William R. Profit and Louis A. Norton), 176;
 Marrow, Cellular Distribution in the, after Thymectomy (A. Corsi and G. V. Guisti), 493;
 Marrow or Spleen Cells, Erythropoiesis in Lethally Irradiated Mice grafted with (A. C. Louwagie, R. Schofield and L. C. Laitha), 370;
 Mineral, Mechanism for the Exchange of the Calcium in (J. Samatoson), 193

"Booby-trapping" as an Alternative to Sterile Males for Insect Control (M. J. Whitten and K. R. Norris), 1136

Book list, October, opp. 366

Books, Where should they be Kept? supplement, 881

Booth, Verne H.: Physical Science, review by E. J. Wenham, 829

Boron Oxide, Emission from Injection of Triethylborane into the Upper Atmosphere (R. C. Millikan), 571

Boulton, A. J.: see under Katrizky, A. R.

INDEX xxxi

Modern Developments in the Mechanics of Continua (edited by Salmon Eskinazi), review by A. J. M. Spencer, 518

Modified Carbohydrate Metabolism in the Tropical Swamp Worm Alma emini (G. C. Coles), 685

Moisture content of food, Nuclear Magnetic Resonance as a Method for Continuously Monitoring Rehydration (G. E. Hall, J. G. Lawrence and R. J. Simpson), 474

Molasses and Urea, Intensive Beef Production from (T. R. Preston, A. Elias, M. B. Willis and T. M. Sutherland), 721

Molecular Basis of Some Aspects of Mental Activity (proceedings), review by H. McIlwain, 723;

Biology of Viruses, The (Symposium), review by John Tooze, 1248;
Biophysics (D. Chapman and R. B. Leslie), review by Peter Sykes, 1353;
Hydrogen in Pre-galactic Gas Clouds (William C. Saslaw and David Zipoy), 976;
Shape and Odour: Pattern Analysis by PAPA (J. E. Amoore, G. Palmieri and E. Wanke), 1084;
Sieving by Glomerular Basement Membrane (Flora Huang, Linda Hutton and Norman Kalant), 87;
Structure of p-carbobenacxy-Glycyl-I-Prolyl-I-Leucyl-Glycine (T. Uk-ki, T. Ashida, M. Kakudo, Y. Sasada and Y. Katsube), 1205;
Theory of Sweet Taste (R. S. Shallenberger and T. E. Acree), 480;
Weight of Human Follicle Stimulating Hormone (C. J. Gray), 1112;
Molecules and Men, Of (F. Crick), review by C. H. Waddington, 202

Molindone, Psychopharmacological Profile of (Alan A. Rubin, Helen C. Yen and Morris Pfeffer), 578

Molluscs (J. E. Morton), review by A. Graham, 894;
Bacteria-free Culture of Oyster Larvae (R. H. Millar and J. M. Scott, 1139;
Isolation of a New Type of Cross Link from the Hinge Ligament (S. O.

Isolation of a New Type of Cross Link from the Hinge Ligament (S. O.

Bacteria-free Culture of Oyster Larvae (R. H. Millar and J. M. Scott,, 1139;
Isolation of a New Type of Cross Link from the Hinge Ligament (S. O. Anderson), 1029;
Nature of the Magnetic Radula in Chitons from Eliat on the Red Sea (M. Eibschutz, E. H. Frei, G. Gorodetsky and H. Steinitz), 1139;
Monitoring Rehydration, Nuclear Magnetic Resonance as a Method for Continuously (G. E. Hall, J. G. Lawrence and R. J. Simpson), 474
Monocytes, Nuclear Pockets in Normal (D. Huhn), 1240
Mon-hydroxo and Mono-fluoro Complexes of Tripositive Cations in the First Transition Series, Charge Transfer in (D. R. Rosseinsky), 791
Monoamine Oxidase Inhibitor, Metabolic Effects of Methionine in Schizophrenic Patients pretreated with a (Yasuo Kakimoto, Isamu Sano, Akira Kanazawa, Takehiko Tsujio and Ziro Kaneko), 1110
Mononucleosis, Establishment of Cell Lines from Peripheral Leucocytes in Infectious (J. H. Pope), 810
Monosacharides, Model for Origin of (Norman W. Gabel and Cyril Ponnampeuma), 453
Monosynaptic Reflex, Effects of Presynaptic and Postsynaptic Inhibition on the Variability of the (P. Rudomin and H. Dutton), 293;
Stochastic Stimulation of Spinal Motoneurones in the Cat (S. J. Redman and D. G. Lampard), 921
Moon, Water on (H. C. Urey), 1094
Moore, Patrick: Basic Astronomy: review by Peter Sykes, 1353;
Walter J.: Seven Solid States, review by R. E. Meads, 899;
Moravscik, Michael (ditor): Recent Developments in Particle Physics, review by S. Zienau, 6 8
More Humane Way with Seals (Elizabeth Simpson), 1237
Morphine-induced Analgesia in Mice, Susceptibility to (Ralph W. Morris and Edward F. Lutsch), 494
Morphogenesis: Computer Simulation of Biological Pattern Generation Processes (Dan Cohen), 246;
Differentiation and Development, Vol. 28 of Comprehensive BioChemistry (edited by Marcel Florkin and Elmer H. Stotz), review by D. E. Newth, 204;
of Shoot Primordia in Cultured Stem Tissue of a Garden Rose (G. P. Hill), 596 Chemistry (edited by Marcel Florkin and Elmer H. Stotz), review by D. E. Newth, 204; of Shoot Primordia in Cultured Stem Tissue of a Garden Rose (G. P. Hill), 596

Morphology of Poly-L-alanine Spherulites (L. C. Anderson, H. Brumberger and R. H. Marchessault), 52

Morris, R. F.: see undar Clark, L. R.

Mortality figures, news, 422

Morton, J. E.: Molluscs, review by A. Graham, 894

John: Guts, review by P. J. Kelly, 1251

Mosquito: Eradication of Culex pipiens fatigans through Cytoplasmic Incompatibility (1. Laven), 383

Mössbauer Spectroscopy of Some Iron Porphyrins (C. I. Wynter, P. Hambright, C. H. Cheek and J. J. Spijkerman), 1103

Motoneurones in the Cat, Monosynaptic Stochastic Stimulation of Spinal (S. J. Redman and D. G. Lampard), 921

Motor Industry, British, news, 9

Mouse Egg, Micropipetting Cytoplasm from the (Teh Ping Lin), 162

Moving Striations, Electron Energy Distributions in (S. W. Rayment and N. D. Twiddy), 674

Mozambique Front in Tanzania, Photogeological Investigation of the (J. V. Hepworth, J. B. Kennerley and R. M. Shackleton), 146

MRC, new head, Dr. J. A. B. Gray, news, 1164

Miller, K.: see under Raub, E.

Multi-Enzyme Analyser, Improved (C. B. Roodyn), 1033

Multi-Sulphur and Oxygen Five- and Six-membered Heterocycles (David S. Breslow and Herman Skolnik) review by J. D. Hobson), 1355

Multiple Analyses on a Single Gel Electrophoresis Preparation (Esther M. Jordan and S. Raymond), 78;

Forms of Cobra Venom Phospholipase A (Beatriz M. Braganca and Y. M. Sambray), 1210;

Schedule of Reinforcement, Selective Action of Pentobarbital on a (R. Stretch, D. E. Blackman and R. J. Bradley), 92

Muons: Tracks in Mica caused by Electron Showers (F. M. Russell), 907

Murine Leukaemia Virus, Influence of Host Age on Leukaemogenesis and Virus Proliferation after Infection with a (Marvin A. Rich, Seung C. Karl and Rodney Clymer), 270;

Lymphocytes, Effect of Phytohaemagglutinin on the Surface Charge of Human and (G. A. Currie), 694

Murray, Dr. P. D. F.: obituary by Alex Stock, 729

Musceles, Ffects

Muscular Contraction by Spinal Neurones in Amphioxus (Branchiostoma lance-olatum), Control of (D. M. Guthrie), 1224 Museums, Educational Services in, news, 424

Mushroom Trays, Virus-like Particles in a Weed Mould growing on (Annemarie Dielman-van Zaayen), 595
Musical Flames (W. R. Babcock, K. L. Baker and A. G. Cattaneo), 676
Mutagenic Capacity of Adenoviruses for Mammalian Cells (H. F. Stich and D. S. Yohn), 1292

INDEX XXXVII

Reserpine in the Rat, Pharmacology of the Mechanism of Certain Effects of (E. Fischer and B. Heller), 1221
Reserpine-induced Hypothermia by Pharmacological Agents other than Antidepressants, Reversal of (B. A. Whittle), 579
Residues, DDT, in Pacific Sea Birds,: a Persistent Insecticide in Marine Food Chains (Robert W. Risebrough, Daniel B. Menzel, D. James Martin, jun. and Harold S. Olcott), 589;
Linked Groups of, in Immunoglobulin K Chains (C. Milstein), 330
Resistance, Coupling, of Double Barrelled Microelectrodes (W. M. Wardell and T. Tomita), 1007;
of Adult Mice to Erythrocyte-bourne Bittner Virus, Lack of (S. Nandi), 809
Resonance in Frozen and Dried Biological Materials, Electron Paramagnetic (R. J. Heckly and R. L. Dimmick), 1003
Respiration and Clicking in Quail Embryos (Margaret A. Vince and S. H. Salter), 582;
In Polyzoa (Ectoprocta) (J. S. Ryland), 1040
Respiratory apparatus: Regulation of Cytochrome Oxidase in Human Cells in Culture (N. Hakami and D. A. Pious), 1087;
Chain and Artificial Membranes, Proton Conductors in the (V. P. Skulachev, A. A. Sharaf and E. A. Liberman), 718;
Quotients in Toad Bladder and Kidney, Significance of (Julius J. Cohen), 399
Response Characteristics of Neurones in an Insect Brain (C. H. Fraser Rowell

Skulachev, A. A. Sharaf and E. A. Liberman), 718;
Quotients in Toad Bladder and Kidney, Significance of (Julius J. Cohen), 399

Response Characteristics of Neurones in an Insect Brain (C. H. Fraser Rowell and Gabriel Horn), 702;
of Euglang gracilis to Polarized Light, Phototactic (K. E. Bound and G. Tollin), 1042;
of Lymphocytes to Penicillin: Comparison with Skin Tests and Circulating Antibodies in Man (Michael J. Fellner, Rudolf L. Baer, Carolyn S. Ripps and Kurt Hirschhorn), 803
to Photoperiod of Reported Long-day and Intermediate Varieties of Rice (B. S. Vergara and R. Lilis), 168;
Resistivity Experiments in New Zealand, Large Scale Earth (P. J. Gill and W. P. Macdonald), 1195
Respiratory Rate of Young Plaice (Pleuronectes platessa L.) in Natural Conditions using Zinc-65, Estimation of the (R. R. C. Edwards), 1335
Retention, Degree of Learning, Proactive Interference and (J. Knight and Jeffrey A. Gray), 406
Reticulo-endothelial system: Inhibition of Multiplication of Foot and Mouth Disease Virus in Adult Mice pretreated with Freund's Complete Adjuvant (D. S. Gorhe), 1242
Reticulum, Sarcoplasmic, Imidazole and Sequestration of Calcium Ions by (B. P. Yuk, E. J. Masoro and F. D. DeMartinis), 822
Retina, Relation between Ganglion Cell Activity and the Local Electroretinogram of Cat (Roy H. Steinberg), 1008
Retinal Cells which produce S-potential, ATPase Activity at the Functional Contacts between (J. A. O'Daly), 1329;
in Rhocospin, Site of Attachment of (Peric Bownds), 1178;
Origin, Cyanopsin, a Visual Pigment of (P. Liebman and G. Entine), 501
Retraction of the Claim that Host Pregnancy affects Pupal Production by the Tsetse Fly (T. A. M. Nash, A. M. Jordan and J. A. Boyle), 163
Reversal of Magnetic field: The North Pacific: an Example of Tectonics on a Sphere, (D. P. McKenzie and R. L. Parker), 1276;
of Reserpine-induced Hypothermia by Pharmacological Agents other than Antidepressants (B. A. Whittle), 579
Reversals, Geomagnetic and Pleistocene Chronology (B. Glass, D. B. Ericson B. C. Heezen, N. D. Opdyke and

tivity and Attractiveness of the Female (J. Herbert and M. R. Trimble), 165;
Monkeys, Adult, Relationship of Sexual Receptivity to Menstrual Cycles in (L. B. Erikson), 299
Rheumatoid Arthritis, Appearance of Specific Acid Phosphatase Isozymes in the Synovial Fluid of Patients with (L. Beckman, G. Beckman and R. Lemperg), 274;
Sera, Inhibition of Complementary Lysis by (J. A. Romeyn and David M. Bowman), 180
Rhipicephalus appandiculatus, Artficial Feeding Technique for, and the Transmission of Thelleria parva from the Salivary Secretion (R. E. Purnell and L. P. Joyner), 484
Rhinolophid Bats in Britain, Longevity of (John H. D. Hooper and Winifred M. Hooper), 1135
Rhodopsin, Site of Attachment of Retinal in (Deric Bownds), 1178
Rhodospirillum rubrum, Inorganic Pyrophosphate and ATP as Energy Donors in Chromatophores from (Margareta Baltscheffsky), 241
Ribosomal RNA, Possible Conformations of 55 (C. R. Cantor), 513;
Synthesis during Normal Cell Differentiation, Attachment of Rapidly Labelled RNA to Polysomes in the Absence of (J. B. Gurdon and P. J. Ford), 666
Ribosome, Internal Organization of the (Rosalind I. Cotter, P. McPhie and W. B. Gratzer), 864
Ribosomes and Polyribosomes during in vivo Erythroid Maturation, Disappearance of (Peter T. Rowley), 1109;
Bonding Radii of 805 (R. S. Morgan and F. D. Kellogg), 1302;
directed by f2 Bacteriophage RNA, GTP-Stimulated Binding of Initiator-tRNA to (John A. Anderson, James E. Dahlberg, Mark S. Bretscher, Michel Revel and Brian F. C. Clark), 1072
Rice and Barnyard Grass, Enzyme Detoxication of 3', 4'—Dichloropropionanilide in, a Factor in Herbicide Selectivity (C. C. Still and O. Kuzirian), 799;
Response to Photoperiod of Reported Long-day and Intermediate

anilide in, a Factor in Herbicide Selectivity (C. C. Still and O. Kuzirian), 799;
Response to Photoperiod of Reported Long-day and Intermediate Varieties of, (B. S. Vergara and R. Lilis), 168
Rift Valley of Kenya, Lake Levels and Quaternary Climates in the Eastern (Celia K. Washbourn), 672
RNA bacteriophage, news, 639;
Effect of Ultraviolet Light on, and Protein Synthesis in Differentiated Epidermal Cells (Kimie Fukuyama, William L. Epstein and John H. Epstein), 1031;
GTP-stimulated Binding of Initiator-tRNA to Ribosomes directed by f2 Bacteriophage RNA (John S. Anderson, James E. Dahlberg, Mark S. Bretscher, Michael Revel and Brian F. C. Clark), 1072;
Internal Organization of the Ribosome (Rosalind I. Cotter, P. McPhie and W. B. Gratzer), 864;
(m) in a Nirenberg Cell Free System, Chemical Radioprotection of (S. Robev and D. Jankova), 1319;
Labelling in Fractions enriched with Neuroglia and Neurones, Kinetics of (P. Volpe and A. Giuditta), 154;
Possible Conformations of 55 Ribosomal (C. R. Cantor), 513;
Rapidly Labelled, Attachment to Polysomes in the Absence of Ribosomal RNA Synthesis during Normal Cell Differentiation (J. B. Gurdon and P. J. Ford), 666;

Sulphur in, news, 431; Synthesis, Determination of Switching-off and Switching-on Time of Overall Nuclear (Y. Doida and S. Okada), 272; Synthesis, Dynamics of, news, 853; Synthesis, Microsomal Protein Synthesis in the Isolated Perfused Liver during Actinomycin Blockage of (J. G. Nievel and W. Dawson), 818:

Liver during Actinomycin blockage of Q. G. Harts. Liver during 818;
T. Messenger, news, 117
Rocket failure, second stage of ELDO launch, news, 1061
Role of Intestinal Lymphatics in Copper Absorption (Irmin Sternlieb, Cornelis J. A. Van Den Hamer and Seymour Alpert), 824;
of Van der Waals Interaction on Hindered Rotation about Single Bonds in Simple Molecules (J. L. DeCoen, G. Elefante, A. M. Liquori and A. Damianii. 910

A. Damiani), 910 Indicated of Man in the Lake District, review by E. E. Evans. 1145

Change on School Leaving

British universities are at last being given their chance to comment on the proposals for a new sixth form curriculum and pattern of examinations which the Schools Council has been preparing in the past year. The Standing Conference on University Entrance has already set in train arrangements for sounding opinion, and its chairman, Sir Robert Aitken, has issued a public denial of reports at the recent Headmasters' Conference that there is at present no means by which a dialogue between the schools and universities on the subject of university entrance can be maintained. Understandably, Sir Robert thinks that the Standing Conference on University Entrance will do the job and he would be within his rights to claim that the Standing Conference was set up precisely so that it could be the negotiating body between the schools and the universities. What remains to be seen is how successfully it can work in the extremely difficult field in which it will be compelled to operate in the months ahead. If it can somehow find a means of winning the agreement of the universities on such controversial proposals as those now to be considered, it will have done wonders. But it is also reasonable to ask whether it would not in the long run be better if the basis of the Standing Conference were somehow broadened. As things are, it is extremely difficult to rouse the interests of university teachers in proposals for reform which do not affect them personally and painfully.

The broad outlines of the Schools Council's proposals are now quite clear. There is to be a pattern in which entrants to university will be selected on the basis of examinations in two subjects at advanced level by methods comparable with those now in use. It is also proposed that students leaving school should follow a number of "elective" courses which may or may not be linked with their chief preoccupations and which will be examined separately, often by the schools themselves. Finally, there is to be a series of courses called "common courses" in the schools intended to provide a broad education for many students but not intended as subjects for examination. If the Schools Council can win the agreement of the universities, it would like to launch an experiment in the schools which could hardly begin before 1969. With luck and good management, it is just possible that the first university entrants under this scheme would make their appearance in 1975 or thereabouts.

Several questions arise immediately. In the first place, there is nothing in the competence of the Schools Council to decide how the universities will make use of the proposed scheme for selecting students. One possibility, of course, is that universities might settle simply for a consideration of the formally examined subjects at Advanced level, which would allow students in the schools to spend more time on unconnected studies but which would also increase the present somewhat arbitrary dependence of would-be undergraduates on the numerical values awarded to them in

the examination. Another possibility, more likely at the beginning, is that a great many university departments would scrutinize not merely the Advanced level examination results but those in the elective subjects as well. If things went badly, the result of that could be that the pressures on the sixth form curriculum by the requirements of university entrance would be substantially unchanged, and that students would be compelled, as now, to choose courses of study at universities before they are old enough to do so wisely. In other words, even if the Schools Council wins approval for its new venture, there is always a danger that the potential advantages in the schools will be perverted by the unwillingness of university departments to change their present habits. And certainly, of course, there is every reason why university chemists or doctors, for example, should insist that it would only be possible to accept the spirit as well as the letter of what the Schools Council is proposing if there were also changes in the pattern of what happens at universities-longer courses, perhaps.

1

It is also unfortunately possible and even likely that the spirit of the proposals will be overwhelmed by the way in which the schools react to them. The most serious objection to the present pattern of education in the schools is that it is too easy for students and particularly bright students to follow narrow courses of study. Although some enlightened establishments may seize on the proposed curriculum as a means of providing a more liberal education, schools which continue to be obsessed with success in winning places at universities may continue to provide a narrow education. In other words, what the Schools Council is proposing is not a means of making sure that modern education in British schools is made more liberal, but merely a starting point from which the schools may be bullied or even shamed into a more independent frame of mind.

In the circumstances it is only natural that the proposals will be attacked from two opposing points of view. There will be many in the universities who say that a less rigid entrance system to the universities will make the quality of university education deteriorate, but this is not merely unfashionable but unimaginative as well. It is impossible to believe that universities could not adapt themselves quickly to the kind of scheme which the Schools Council has devised, particularly if one of the benefits were to be recruitment of more able and more liberally educated students from the schools. It will be a great shame if arguments like these prevail.

The more serious objection to the proposals is that they do not go far enough, and it will certainly be hard for anyone to suppress the question of whether it is feasible to wait until 1975 for the radical revision of the school curriculum which has been an urgent need for several decades. But the nature of the proposed reforms also leaves much to be desired. In particular, they do not offer the urgently necessary assurance that school

education will become more liberal and the careers of undergraduates at the universities much less closely predetermined. This is why the universities will do well, in the discussions which lie ahead, to ask whether the Schools Council's proposals could at this stage be replaced by a much more radical and rewarding scheme. For one thing, it would seem essential that a real broadening of the curriculum should somehow be attained, and an obvious way of doing this is to encourage a pattern in which university entrants follow more obligatory courses and not fewer. But it is also important to explore the consequences for the universities of the present difficulty of recruiting a diversity

of students into specialized departments at the universities. Are four years essential after all? Or is it possible that a shorter long vacation would solve a lot of problems? Because these and other questions are inevitably bound up with a thorough discussion of what the Schools Council is proposing, it is inevitable that the Standing Conference on University Entrance will have to fight a great many battles in the months ahead. Its success will depend not just on winning agreement of some kind or another but on the vigour with which it can push the universities in the direction of more radical reforms, however unpleasant and unfashionable they may seem.

What Professor Flowers Should Do

THE appointment of Professor B. H. Flowers as chairman of the Science Research Council from the beginning of this month is an important development if only because it provides an opportunity for the council to find a permanent pattern of operations. The council as it is at present is still clearly the rump of the old Department of Scientific and Industrial Research, principally because of its involvement in the support of university research and postgraduate education. But the past decade has been one long sequence of upheavals. First there was the Jephcott Committee, which changed the relationship between the council of part-timers and the full-time staff. Then came the dismemberment of the department in the aftermath of the Prend Report and the election of the Labour Government in 1964. At various times in this short period, the department has been financially responsible to the Lord President of the Council and to the Department of Education and Science. At the beginning it was a more or less free-living organism, but now its activities are controlled to some extent at least by the Council for Scientific Policy. In the circumstances it is not surprising that the Science Research Council has failed so far to create as clear an image as it should have. It is also relevant that in the United States the National Science Foundation is also having difficulty in persuading scientists that it can be counted on as an effective intermediary between the government and research. The most obvious difficulty is the sheer diversity of the work on which both organizations are engaged.

This, fortunately, is a pointer to an immediate need in the planning of what the Science Research Council should attempt in the months immediately ahead. For one thing, there is a need somehow to create a feeling among professional scientists that the Science Research Council is on their side and not, for example, that of the Treasury. There is no shortage of causes by means of which demonstrations like

What Price for Electricity?

THE British electricity generating industry probably cannot help creating the impression that it speaks with two voices on prices. Only a few weeks ago,

these could be arranged. The way in which the employment of the council's own staff at laboratories such as Daresbury is plagued by troubles about pensions (see page 5) is an obvious place at which to start. Behind the scenes, no doubt, the Science Research Council has been as vigorous as anybody in doing battle with the Treasury on this issue. But there is no reason why it should not fight this kind of battle more openly. It would certainly thereby command the confidence of scientists more easily. It might also win more often.

These, however, are comparatively minor issues. In the long run the effectiveness of the Science Research Council as a focus for the financing of fundamental research in Britain will depend on the capacity to anticipate the changing needs of various kinds of research. It must learn to take the initiative and not wait on events as it often seems to have to do. The most obvious way of winning a reputation in this field would be to re-create within the council some of the planning functions which used to flourish in the days of the Department of Scientific and Industrial Research and then to strengthen them enormously. In other words the Science Research Council would do well to create some means of knowing in advance just where the new developments in academic science are likely to need more generous support. It has made a start in this direction in the past few years by setting up machinery for exploring new avenues of research in biology. It is also enormously to be admired for the way in which it has converted astronomy in Britain into a flourishing field of research. But these are necessarily isolated and even sporadic initiatives. What is needed now is some means of taking a grip on the whole development of academic science and on a good deal of policy on higher education in science as well. Here again, it is no accident that the National Science Foundation in the United States has set its heart on such a development, so far without conspicuous success.

there was a storm because the Government had sanctioned increases in retail prices for electricity working out, on the average, at 15 per cent or so.

But earlier this week the Chairman of the Electricity Council, Sir Ronald Edwards, took the occasion of the publication of its annual report and that of the Central Electricity Generating Board (House of Commons Papers 625 and 626, HMSO, 16s. 6d, and 10s. 6d. respectively) as a chance to draw attention to the way in which nuclear power stations now promise to be substantially cheaper than the conventional variety. The detailed proof that an advanced gas cooled reactor can produce electricity at 0.48d. per kilowatt hour, compared with 0.58d. for a conventional plant in exactly similar circumstances, will no doubt put an end to the confusion there has been in the past year on just this issue. Lord Robens, speaking on behalf of the coal industry, has been particularly diligent in clouding this issue. But does it therefore follow that the electricity industry will promptly give up the construction of other kinds of power stations than those based on uranium, and does it follow that the price of electricity will eventually be reduced? The simple answer to the first question is that it would be unwise for the Central Electricity Generating Board to take hard and fast decisions at this point. Left to itself, of course, it is unlikely that it would build coal burning power stations. But there is always the possibility that natural gas could be a cheaper source of fuel, particularly where off-peak supplies of power are necessary. any case, there is still room in the British electricity system for small packages of power produced from oil. Although there has been a further small improvement in the average load factor, with the result that in 1966-67 the 34,000 megawatts of generating capacity were in use for 52 per cent of the time, there are still very large variations in the demand for electricity from one time of the year to another. The smallest demand on the system is still less than 10,000 megawatts on many occasions, and this is a measure of how little room there is in the system for the building of nuclear power stations which must, by their nature, operate at a high load factor if they are to do so economically. This, however, does not imply that there is any cause for the electricity board—and the Atomic Energy Authority—to mute their celebrations of the way in which advanced gas cooled reactors seem to have provided them with new opportunities. And it is perhaps churlish to remember that only five years ago, when the first advanced gas cooled reactor prototype was being built, the electricity people were sceptical and even resentful of the development.

It does not unfortunately follow that the planning of the future pattern of power generation will be conducted by the simple rules of pure reason. By all accounts, the Ministry of Power is about to produce a new White Paper on fuel policy for the 1970s—Mr Richard Marsh said as much when he spoke at Scarborough earlier this week. The difficulty is that in the present economic climate, in which resistances to change are reinforced by what seems to be adversity, there is a serious danger that too much concern for keeping collieries in being will set a precedent of protection that will last well beyond the immediate

crisis into the decade ahead. Mr Marsh was saying as recently as July that he was determined in the seventies to see full-blooded competition in terms of price between alternative kinds of fuel. But he has had an uncomfortable time since then. Will he still be able to write a White Paper based on the assumption of equal competition, and will he go as far as saying that it is not for the Ministry of Power but for the electricity boards to decide how to manufacture electricity most cheaply? These are the tests by which his policies should be judged.

The confusion about price is likely to persist, particularly now that the cost of generating electricity is a declining percentage of the cost of operating the industry as a whole. So much is clear from the annual report now published. The cost of transmission is by contrast an increasing burden. The generation of electricity, on the average, worked out in 1966-67 at 0.792d. per kilowatt hour, which is less than half the total expenditure of the industry in supplying a unit of electricity—1.767d. In circumstances like these, it is evident that savings of the order of 20 per cent on the cost of generation at base load power stations will not make comparable savings in the cost of providing electricity to customers. Indeed, the industry will be lucky if the coming into service of nuclear power stations enables it to keep the cost of generation And there is very little doubt that the Minister of Power could do more than any engineer to reduce the price of electricity in the immediate future. He could, for example, take steps to remove the anomaly by means of which the electricity industry pays a tax on fuel oil which is not levied on the gas producers. And there is obviously great scope for a more thorough examination of the principle on which the electricity industry is required to earn each year a surplus of more than 12 per cent of the capital employed.

But does not public subvention for the development of nuclear power stations amount to a kind of subsidy for electricity? This is also a question which the Minister of Power and the electricity boards should face. Theoretically, the industry will pay a royalty on each advanced gas cooled reactor which it builds particularly so as to recompense the Atomic Energy Authority for the developments already carried out. But what if the advanced gas cooled reactor had been a failure? Then there would have been no royalties to pay. In other words, it does appear that the separate development of new kinds of reactors by the Atomic Energy Authority is a means by which the electricity industry is shielded from the risks of new developments. So should the development of new reactors be handed over to the Central Electricity Generating Board? This, no doubt, would be a course of action that would simplify the problems of the Ministry of Technology which cannot much longer postpone decisions on the future of the Atomic Energy Authority. But a marriage of this kind between the two authorities would undermine the chances that British reactors will be sold elsewhere. The ideal is, rather, some partnership between the two organizations by means of which the risks of new developments could be more accurately apportioned. If they were private companies the solution would be simple—one would buy a stake in the other. Is it entirely outrageous therefore to suggest that there should be some common membership between the Central Electricity Generating Board

and the Atomic Energy Authority? In the long run that would be an effective means of making sure that new reactor developments were likely to find a ready customer. In the immediate future it would help to ensure that the present unnecessary, let alone wasteful, duplication of research laboratories by the two organizations could be somehow done away with.

Prices for Drugs

THE trade association for the British pharmaceutical industry has reacted vigorously to the publication last week of the Report of the Government Committee which has been studying the relationship between the pharmaceutical industry and the National Health Service (Cmnd 3410, HMSO, 17s. 6d.). The principal recommendations of the Sainsbury Committee are that there should be established an independent medicines commission with power to license the introduction of new drugs, to regulate their use, to help doctors decide which medicines should best be employed and to control advertising of drugs. The report also says that the Ministry of Health should be empowered to obtain from manufacturers detailed statements of the cost of individual drugs and that it should be able to determine prices paid for drugs supplied to the National Health Service on the basis of a reasonable return on the capital employed. In its reply to the report, the Association of the British Pharmaceutical Industry says that some of the recommendations of the Sainsbury Committee would "effectively amount to state control" of the industry. The association takes the line that the Sainsbury Committee may have been misled in arriving at its views on present pricing policies in the industry by the profits earned by a small number of companies.

However this dispute may be resolved, the Sainsbury Committee will have done a considerable service by providing a detailed picture of the state of the British pharmaceutical industry. The total output of the industry amounts to roughly £250 million a year, and between 55 and 68 companies account for more than 95 per cent of the total value of materials supplied to the National Health Service. Of the medicines supplied on prescriptions in 1966, 27 per cent came from British companies, nearly a half (by value) from companies controlled from the United States and the rest from companies controlled from the mainland of Europe. Exports run at about £30 million a year net. The value of drugs supplied to the National Health Service has risen over the years, largely because of the increasing proportion of proprietary medicines now used in the National Health Service, from £43.6 million in 1949 to £173.5 million in 1965. The views of the Sainsbury Committee on drug prices are based on an analysis of the profitability of 27 important companies each selling more than £1 million worth of drugs to the National Health Service each year. Seventeen of these companies earn profits of more than 20 per cent of the capital employed and 8 of these had rates of profit exceeding 30 per cent. Not all companies, however, were equally prosperous. Four of them earned profits in the three years 1963-65 which work out at less than 10 per cent of their capital employed. In its comment on these figures, the committee suggests that drugs supplied to the National Health Service in the early sixties may have been priced excessively "to the extent

of several million pounds". It rejects the view that high profitability is necessary if companies are to be encouraged to undertake research on a sufficient scale by saying that "firms which have sustained a research programme involving a substantial number of research personnel have emerged with encouraging regularity with products which have remained dominant in their field of therapy for a considerable time".

In the industry as a whole, the amount spent on research directly related to National Health Service products in 1965 was £16 million, or 9.7 per cent of the total sales of National Health Service drugs. Altogether, fundamental research aimed at the production of entirely new products seems to have accounted for between 56 and 58 per cent of the total research bill. By comparison, process development took much smaller sums of money—13.5 per cent. Because of the way in which many of the companies which operate in Britain make use of research carried out elsewhere, it appears that more than £3 million each year should be added to the value of the work done in British laboratories. The Sainsbury Committee suggests that some of the work classified by companies as fundamental research may not always deserve that name, but nevertheless considers that the figures available do not support assertions that the industry neglects long-term work. The committee does, however, consider that there could be closer links between the companies and the universities. All this implies that the pattern of research in the British pharmaceutical industry is unlikely to be seriously disturbed by the appearance of the Sainsbury report.

Double or Nothing

THE launching of a new communications satellite over the Pacific last week should make the advocates of a fifth transatlantic telephone cable rush to put in a good word for cables. But what is it? Reliability, perhaps, or longevity or familiarity; the same arguments would do for the horse. The fact is that new cables can only add to existing capacity, while satellites can almost multiply it. Cables allow only pointto-point communication; satellites can allow many to talk at once. Even from a political point of view, they are more forward looking. Telephone calls from one underdeveloped country to another usually have to be routed through one of the old centres of power-New York, London, Tokyo or Paris. But with satellites, just as distance means nothing (once it is 22,300 miles up), neither do national or natural boundaries.

Much has been made by those who hanker after cables—among whom are included the conventional communications carriers in the most articulate countries—of the failure of the first INTELSAT II satellite to achieve its proper orbit last autumn. But even that

functioned for about eight hours a day and its successor a few months later made available, all around the clock, all types of telecommunications between the Pacific Coast of the United States and the Far East. The Pacific satellites have done something more: brought down cable rates. The trans-Pacific charges set by Comsat, the United States Communications Satellite Corporation, were so much lower than those set by the cable carriers that the Federal Communications Commission ordered these to cut their prices or let Comsat take over their business with the American defence department. This is why the American Telephone and Telegraph Company is now preparing another cut in trans-Atlantic rates, presumably to match the satellite competition.

The economics of satellites are uncertain. The first sent over the Pacific was, in a sense, a waste of money (although a failure rate of one in five launchings has been budgeted for). It is no longer in use. But Early Bird has been working a full year longer than expected on the Atlantic run; estimates for the lifetime of satellites have been deliberately pessimistic. The chances that they will be cheaper than anyone thought are probably better than that they will be more expensive.

The recent launch put the fourth INTELSAT II into the sky. (One is over the mid-Atlantic, where it can make up for the inability of Early Bird to provide links with the southern hemisphere as well as simultaneous television and telephone transmission.) The newest has been sent into synchronous equatorial orbit over the Pacific at approximately 175 degrees East. All are about twice the weight of Early Bird, weigh about 192 pounds and are 56 inches in diameter and 26.5 inches high, not counting antennae. Next year, however, the stout string and sealing wax stage should be over for good.

The INTELSAT III series of satellites should by then have been launched, all six of them. Built by TRW Incorporated for a basic price of \$32 million, these will have three times the capacity of the INTEL-SAT II satellites and should ensure continuous operation, even if one or even two go dead. By 1969, moreover, the total number of ground stations around the globe is expected to be 40—including one in Spain, which is also being mentioned as a possible terminus for the new telephone cable.

Victory on Pensions

The Institution of Professional Civil Servants seems to have won a tangible if modest victory in its dealings with the Department of Education and Science on behalf of scientists working for the research councils who may find themselves being transferred to the British Civil Service. The issue is the ease with which people moving into or out of the Civil Service can retain their pension rights in full. Hitherto transfers of this kind, an increasingly common hazard now that public laboratories of all kinds are beginning to respond to the public clamour for mobility, have been governed by the rule that entitlement to pension is within the discretion of the Civil Service. Although the research councils and the Civil Service operate pensions schemes which are closely similar, and which are in particular non-contributory, it has been possible for the Civil Service to take an awkward line in its dealings with transfers. Sometimes, for example, the question has been raised of whether people leaving a Civil Service laboratory for a job with one of the research councils have had no assurance that the full value of their pensions rights would be transferred. seems now to have happened is that the Institution of Professional Civil Servants has won the agreement of Mr Patrick Gordon-Walker, Secretary of State at the Department of Education and Science, that transferability would in future be automatic for movements between the Civil Service and the research councils. Transferability between the Civil Service and the research councils on the one hand and the rest of the world on the other continues to be impeded by lack of transfer rights, although it is hard to see how the Fulton Commission on the Civil Service can fail to recommend the abolition of this anomaly.

News of the dispute between the Institution of Professional Civil Servants and the Science Research Council about the pensions rights of those employed at the Daresbury Laboratory is less cheerful. A writ against the council by the institution is due to be heard in the courts later this year. The issue is exceedingly complicated, chiefly because of the reorganization of government science under the Science and Technology Act of 1965. The act was the legal instrument which established the Science Research Council and which transferred to it the activities of the National Institute for Research in Nuclear Science, then the operator of the Rutherford Laboratory at Harwell and the body responsible for building the Daresbury Laboratory. Because the Rutherford Laboratory had grown out of the Atomic Energy Authority's laboratory at Harwell, it had been agreed that employees at the Rutherford Laboratory should retain, if they chose, membership of the contributory pensions scheme operated by the AEA. The need to perpetuate this arrangement under the new legislation was apparently recognized only at a late stage of the passage of the bill through Parliament, and an amending clause was introduced in February 1955. This clause laid down that the right to opt for AEA pensions should apply not merely to those already "employed by the National Institute for Research in Nuclear Science" but also to those subsequently taken on "to work on activities taken over ... from the National Institute for Research in Nuclear Science", but Lord Snow told the House of Lords at the time that there was no intention that this provision should apply to Daresbury as well as the Rutherford Laboratory. The Institution of Professional Civil Servants has taken issue with the British Government's view that the Act will permit such an Whatever the courts decide, it is interpretation. hard to think that these arrangements will survive the acid test of feasibility, let alone the report of the Fulton Commission now only half a year away.

Aldabra Expedition Returns

THE first phase of the Royal Society expedition to Aldabra, the atoll in the Indian Ocean where the Ministry of Defence proposes to build an air staging post and the BBC would like a transmitter, is now complete. Seven scientists have returned after spending five weeks on the atoll, making preliminary investigations of numbers and distribution of animals and plants, both on the atoll and in the lagoon. They have come back convinced that Aldabrashould be preserved,

for it is the last place in the Indian Ocean where island life can be studied in isolation.

The expedition landed at the west island, where there has been a settlement since 1888, and from there made excursions to the south and north, and, together with parties from the Ministries of Defence and Public Building and Works, to the east end of the atoll. The aim was for each member to become acquainted with as many habitats as possible. The eastern end proved to be the area of greatest ecological interest. It has the greatest concentration of giant land tortoises, Testudo gigantea. There are apparently more than 10,000 of these tortoises on Aldabra; elsewhere they are only found in the Galapagos Islands. The eastern end has also the greatest number of frigate birds, as many as a thousand birds could be seen hanging above one of the fresh water pools which attract them. The main breeding area of these birds is in the middle island where hundreds of thousands were seen nesting.

This survey work is being continued by four scientists and two technicians of the Royal Society party who remained on Aldabra to carry out the second phase of the expedition. If the Ministry of Defence project is not implemented, a long term thorough ecological survey will be planned; if the project goes ahead the expedition will make the fullest possible ecological survey before the ecology of the atoll is changed by the construction work.

Aldabra has remained untouched because it is so inhospitable to man; the terrain is difficult and apart from rain there is very little drinking water. proposed developments will be extensive, and the whole ecology will suffer. When construction begins the weeds which are associated with settlements, and which are now contained by the native vegetation, will spread through Aldabra. There will be a flow of foreign weeds and invertebrates into the islands, and the feral mammals now confined to the south and west islands will spread throughout the atoll. When the cats find the flightless rails these birds will not last very long. The danger is not, however, of large scale extinction; the RAF would make efforts to preserve the giant tortoise and flightless rail, which in any case can be preserved in zoos. The inevitable consequence of construction work will be the destruction of the integrity of an unspoiled island ecosystem. This is the last remaining ecosystem of its kind in the Indian or Pacific Oceans, and that for the Royal Society is reason enough for preserving it.

Money for Chemists

The Chemical Society is appealing to its members for money. This is not because of careless accountancy—in fact the society seems to have been scrupulously careful—but is one result of a move which the society plans to make to the rooms occupied until recently by the Royal Society in Burlington House. The Royal Society itself has moved to Carlton House Terrace, and most of the rooms left empty have been offered to the Chemical Society rent free by the British Government. The snag is that the move will be expensive—the society estimates that it will need £300,000 to adapt and furnish the new rooms, build a new publications warehouse at Letchworth and share the cost of a new lecture theatre in Savile Row. By what it describes as prudent husbanding of its re-

sources, the society has saved £125,000, and is now appealing to its members, to the chemical industry and to charitable trusts for the extra £175,000.

Chemists who feel that this is an expensive move should reflect that the new rooms will enable the society to group together staff previously distributed all over London. It will also provide a council room and a much larger library. They might also be reminded that it has cost the Royal Society £863,000 for its move to Carlton House Terrace. £250,000 was supplied by the Government, and an equal sum by the Nuffield Foundation, but much of the remainder is still outstanding. Ominously for the Chemical Society's hopes, an appeal to fellows of the Royal Society has not so far produced everything the organizers hoped for. And gratitude to the Government for its generosity in supplying accommodation should perhaps be tempered by the thought that once there were splendid hopes for a home for scientific societies in a science centre on the South Bank. It is a long time since that idea was last heard of.

Temptations of Science

THE British preoccupation with the need to persuade young people into science and engineering, but particularly the latter, was continued last week by the Research and Development Society, which devoted the second of its one-day symposia to the subject. Adults. at least, are prepared to take the subject seriously, and 150 turned up at Imperial College to listen to a panel of speakers which included many of those whose names are now associated with the definition of various aspects of this problem—Professor Michael Swann, for example, and Mr G. S. Bosworth, Director of Personnel at the English Electric Company. Mr Bosworth was strong in his statement that "technology is not a second-rate science". To pretend otherwise is now, of course the most sure way in which a man can lose his public reputation. But Mr Bosworth also said that engineers are too often diverted from the objectives by irrelevant details in atomic theory, and that industry often mistreats those whom it recruits so that they hurry back to the "world of the PhD". Mr D. A. Head, from the aero-engine division of Rolls Royce, took the line that, however the difficulties of attracting scientists into industry have arisen, only industry can handle the problems thus created, which means that companies must put recruits into the right jobs and make sure that they know about their prospects of promotion.

The symposium seemed to agree about the shortcomings of education in British schools and universities. For one thing, there was a general complaint about early specialization, one of the consequences of which is the alleged reluctance of narrowly educated people in industry to change from one kind of job to another. On the whole, those attending the conference took the view that specialization should be postponed until 18. There was also a general feeling that science courses at universities should be broadened so as to provide students with an appreciation of other kinds of studies and of social problems of various kinds. One speaker went so far as to say that the British educational system is designed to produce "cultured gentlemen", with the result that trained scientists consider that collaboration is a kind of cheating, that engineering is inferior and that the profit motive is even worse.

Yet teamwork, technology and business sense are essential for the survival of the British economy.

But what if you cannot even bring the horse to the water, let alone persuade him to drink properly? The symposium depressed itself with speculation about the reasons why young people may now be reluctant to go in for science and technology. Again there seemed to be general agreement that the young are infected with a "new fatalism" and have no vision of a golden future to which science and technology may contribute and no inkling of the enthusiasm which professional scientists have for their work. It was all good gloomy stuff. One of these days something may be done about it.

Instant Teachers

How long does it take to turn a student of the humanities into a science teacher? Three years is the answer given by Nottingham Regional College of Technology. In its new Department of Education, Nottingham is basing its acceptance of candidates for its three year Certificate of Education course in science teaching on general ability and interest in science teaching as well as academic qualifications in science. Thus if a candidate can demonstrate his ability in other subjects and his interest in science teaching, the college will accept him even if he does not know one end of a thermometer from the other.

Because of the shortage in applications from science candidates to teacher training colleges and universities, the department has decided not to compete for pure scientists but to offer Applied Science and a second opportunity to those who opted for the humanities instead of science at school. As the courses are designed for the Nuffield programme of science teaching, where a feel for the subject is much more important than facts, it is hoped that general ability will make up for any lack of specific knowledge.

The courses will tend towards either Biological Sciences or Physical Sciences and an Engineering course is under discussion. The students of the physical sciences will spend four terms working on American courses, which start from first principles for beginners but allow scientists to be rapidly directed into more profitable work. The teaching scheme is based on individual study rather than lecture programmes, and tutors will make much use of written material, acting as directors of study and tailoring the work to each student's needs. Students will also be able to take short courses from a range which will include Computer Science, Chemical Technology, Building Science, Food Science, Materials Science and Mechanical Engineering. These short courses should enable the students to base their teaching on practical applications when they go into the schools.

Nottingham Regional College of Technology is one of five technical colleges—the others are John Dalton College, Manchester, Sunderland Technical College, Barking Regional College of Technology and North Western Polytechnic-which are now running courses for the Certificate of Education. Previously these three year courses could only be taken at Colleges of Education. The Principal Lecturer, in charge of the science courses at Nottingham, is Dr Michael Bassey, who will be remembered for his trenchant criticisms of school science syllabuses at the British Association meeting in 1961.

More Cancer Research

A NEW research block consisting of laboratories for Tumour Immunology and Radiobiology was opened at Sutton, Surrey, on September 27. The unit is part of the Chester Beatty Research Institute, and the £150,000 it cost has come from the Napier Trust, the British Empire Cancer Campaign, the Medical Research Council and other donations. Block X, as it is called, has been operational since June, only 17 months after the idea for such a unit was suggested. Because the unit is alongside the Sutton branch of the Royal Marsden Hospital, it is hoped that any positive results that are obtained will be speedily applied.

Work has been going on for some time on various forms of immunotherapy, and in particular the treatment of primary sarcomata by injection of either immunized lymphocytes or of immunized cancer cells, that is, cells taken from the tumour, after removal by surgery, and rendered "sterile" by irradiation. Some of the impetus for the new research unit has come from research described earlier this year by Alexander, Delorme, Hamilton and Hall (Nature, 213, 569). Evidence has been found in animals of host resistance to tumours, and it is hoped that by boosting this reaction by the injection of immune lymphocytes it will be possible to provide some control. This form of treatment would be particularly important after surgery.

Under some conditions this treatment has proved successful in experimental animals, but it is emphasized by the staff of the new unit that experience of this treatment is too limited for any definite conclusions to be drawn. The mechanism of the cytotoxic action of

lymphocytes is also being studied.

American workers S. H. Nadler and G. E. Moore have also carried out transplant experiments in which tumours from two patients were transplanted to each other and after 10-14 days lymphocytes from each patient were transfused back to the other to fight the original growth. In several cases remission of the cancer for considerable lengths of time has occurred. This method of treatment is also being considered for investigation at the new unit.

Refining Steel

ELECTRO-SLAG Refining Technology, the British Iron and Steel Research Association's first development unit which was formed to exploit the electro-slag refining process, has fully justified its existence in its 15 months of operation on a commercial basis. It has recorded widespread use of its hire and contract facilities and has been responsible for a number of technical developments. Five plant manufacturers have entered into agreements with ESRT, and have installed or are installing fourteen plants with ingot producing capacities ranging from 8 to 36 in. The unit has also supplied 250 ingots to some twenty-five customers, covering a range of thirty-five alloys. ingots have enabled customers to evaluate the electroslag refining process. 224 ingots have been made on a miniature plant in thirty-eight individual contract evaluation programmes for fourteen clients. result of these studies, techniques have been developed for production melting of many alloys both in Britain

Electro-slag refining is a secondary refining process

for producing quality controlled steels and alloys in fairly high tonnages. It is economically competitive with other processes at present used, as the capital outlay is fairly low and the running cost is the same as if not cheaper than the other processes.

Shocks in Store

THE bid by the General Electric Company for Associated Electrical Industries seems to have taken AEI by surprise. AEI is taking a week to think about the bid, worth £120 million in stock and cash, before committing itself to a view. GEC has offered five GEC shares and 80s. cash for every eight AEI shares, which effectively puts a value of 52s. 1d. on the AEI shares against a market price before the bid of 43s. 6d. By October 3, AEI shares stood at 56s. 4.5d., as high as they have been this year, indicating a feeling among investors that AEI will offer at least some opposition to the takeover. The terms, AEI is likely to claim, are based on a poor performance by AEI last year, and a forecast of profits of about £9.2 million this year. It is likely to add that better times are on the way, but shareholders have been told this many times before. GEC profits are far more buoyant, running at about twice those of AEI, although GEC is a much smaller group.

Both companies employ large research departments. AEI has a large central research laboratory at Rugby, which carries out basic research for the whole company as well as contract research work for government and other companies. AEI Power Group has a laboratory at Trafford Park in Manchester which includes among its interests scientific instruments, traction and magnetohydrodynamic power generation. The Telecommunications Group runs two laboratories, one at Blackheath and one at Harlow, and the Cables Group has a laboratory at Gravesend concerned with insulating materials, and one at Woolwich studying high voltage phenomena. The joint AEI-Thorn semiconductor company also runs a research department.

GEC's main laboratory is the Hirst Research Centre in North Wembley, named after Sir Hugo Hirst, the founder of the company. This has divisions serving all branches of the business—lamps and lighting, telecommunications, electronics, valves and semiconductors. It also includes three divisions doing more fundamental work, in engineering, metallurgy and electronics materials, and a division which supplies chemical and technical services. In addition, GEC Electronics runs two applied electronics laboratories, at Stanmore and Portsmouth, and there is another telecommunications laboratory at Coventry. The Osram lamp company has two laboratories, and other companies associated with GEC also run their own development laboratories.

If the takeover goes through, some rationalization of this mass of laboratories seems inevitable. This is particularly likely in electronics, where the new group would hold 40 per cent of the market. GEC has a joint semiconductor company with Mullard, while AEI shares its electronics interests with Thorn; if the deal is successful, GEC hopes to merge these interests and save money on research. It is not yet clear how the deal would affect AEI's nuclear power interests—it owns 10 per cent of the shares of the Nuclear Power Group, Ltd. GEC's association with

nuclear power ended some years ago, and was not a happy one. GEC was involved in the building of an unsuccessful power station in Japan, and still has problems to solve at the Hunterston A station which it built. AEI's nuclear power interests have certainly been more profitable than this, but whether this would encourage GEC to go back into nuclear power as part of the Nuclear Power Group, or pull out altogether, is still not clear.

Laboratory of All Trades

SEWAGE is unattractive but inescapable. At the Water Pollution Research Laboratory, the staff continues to study it with every evidence of enthusiasm, and this year is spending £360,000 both on the treatment of sewage and on its effects when allowed to escape. A scheme in collaboration with the Hydraulics Research Station and a firm of consulting engineers is intended to find the ideal position for sewage outflow in the Thames Estuary. In parallel, the laboratory is studying the effect of pollution on fish, together with the related problems of the variation and measurement of oxygen concentration in streams and rivers.

The laboratory has been hard at work on the two chief methods of biological treatment—the activated sludge process and biological filtration. One interesting development is the use of plastic filters in biological filtration, and a system has been devised for controlling automatically the intensity of aeration so as to maintain oxygen at an optimum concentration. A new treatment of sewage, by chemical oxidation at high temperatures and pressures, is undergoing preliminary investigation, and as a means of reaching high pressures it has been suggested that the sewage be poured into very deep holes in the ground. The laboratory is optimistic about the change from hard to soft detergents; this, it says, has had the effect of markedly reducing the amount of foam in rivers. The manufacturers and the laboratory are hoping to find even softer detergents, and are conducting an experimentat a small sewage works serving a village community specially supplied with experimental detergent by the manufacturers.

Pollutants are also studied at the Warren Spring Laboratory, but in this case air is the dispersion medium. The laboratory provided background information for the Clean Air Act and is at present completing a five-year national survey of smoke and sulphur dioxide. Smoke concentration in the air has been falling, and although total emission of sulphur dioxide has risen slightly, the overall concentration of the gas has fallen.

Recovery of metals from scrap, studies of process control and separation of dry minerals by air fluidization form an important part of the work of the mineral science and technology section and the chemical engineering section. Both work in consultation with industry. The chemical engineering section has considerable interest in catalysts. A pilot plant producing acetone by dehydrogenation of isopropanol has been linked to a computer for process control studies, but this system has limited application. Control by simple logic systems of batch processes such as distillation of binary mixtures is being studied and is likely to be more useful. The laboratory employs a staff of 440, and is expanding slightly year by year, with annual expenditure standing currently at £1 million.

An Industry in Hard Times

By our Special Correspondent

The British motor industry has had a hard year, and the winter is still ahead.

Although more than a year has passed since the crisis measures of July 20, 1966, the British motor industry has not forgotten them. The combination of a freeze on wages and pressure on credit which Mr Wilson prescribed gave the industry the most uncomfortable autumn and winter it can remember. All the manufacturers suffered, but the worst hit was the British Motor Corporation, which declared 12,000 men redundant—and lost another 3,500 who decided that they would be better off elsewhere. BMC made a loss of £7.5 million in the first six months of the financial year, and the second half report, still to come, will show only a small profit. There is little doubt that the other motor companies did badly over the same period, but they may have been saved some embarrassment by not having to produce a financial statement quite so soon.

The crisis at BMC has left a legacy. It has been traditional for BMC to take the largest share of the British market—usually around 40 per cent—but now its share is down to 32 per cent. Even this is not as bad as the 29 per cent to which it was reduced at the height of the crisis. People are now openly doubting whether BMC will be able to regain its dominance in the market without a new range of models. The Mini, now eight years old and continuing in virtually its original form, is too small as a basic unit. The 1100 model, the next in the range, is too expensive and the 1800 range has not been a success. By an unhappy blunder, BMC hardly competes in the 1.5 litre range, where Ford finds all its profits. In the bigger sizes, BMC has a positive embarrassment of models since it took over the Jaguar company, but all of them are beginning to look dated.

To some extent, BMC's troubles can be traced to an unwillingness to take full advantage of its size. Although the merger between the Nuffield organization and Austin took place 15 years ago, only in the last two or three years have the demarcation lines between the two organizations disappeared. Worse still, BMC still sees it as its duty to perpetuate the names of Riley and Wolseley—and others—by decorating perfectly honest Austins with the trappings of the more luxurious makes, walnut facias and all. It is surprising that supporters of the old marques are satisfied with such unconvincing imitations. Next year BMC will make a tentative step in the right direction by abolishing the distinction between Austin and Morris in the commercial vehicle field, but progress towards unification is slow.

The multiplicity of models is matched by a geographical diversity of factories. The whole British Motor Holdings group, including BMC, Jaguar and Pressed Steel-Fisher, controls 26 factories. There are at least two reasons for this; on the one hand, mergers have provided factories everywhere in Britain and, on the other, the group has been persuaded by the government to open new factories in depressed areas—Bathgate in West Lothian, and Llanelly in Wales. The results of this are unfortunate. To take one example, exhaust systems for the group are made at Morris Radiators plant in Oxford at the rate of 30,000

a week. But the actual silencers are made in Llanelly and taken across country by road for assembly into complete systems. After assembly, the systems are once again packed up and distributed by road to Longbridge and Cowley. Car doors are made in Llanelly, and transported to the main factories, again by road. This certainly introduces extra costs which a fully integrated plant avoids.

There are more optimistic signs. At Longbridge, BMC is building an integrated plant for the manufacture of engines. When finished, the new plant will be able to handle 5,000 engines a week on a highly automated assembly line controlled by computers. This development, which is to cost £16 million, will produce its first engines by the end of this year if there are no further delays—it is already four months behind schedule. Near Oxford, BMC has built a new spares warehouse as part of the service department. This project has cost £6 million, and should provide BMC with one of the most efficient spares services in the world

These developments, and others, will be financed out of profits if BMC can start making them again. Much will depend on the economic climate. The other British motor companies will get only a small measure of satisfaction from BMC's discomfiture, principally because they are in almost as unhappy a position themselves. Ford's profit margins, once the wonder of other manufacturers, have been winnowed away over the years until they are little better than the rest. Only the Cortina in Ford's range is making money. Rootes, meanwhile, have found the experiment of going to Scotland to build their Imp range is not a success, and are currently ringing the changes on a basic model which is selling very slowly indeed. Vauxhall is troubled by labour stoppages and by the fear that its American owner, General Motors, favours a European marketing policy based on Opel, its German subsidiary, rather than on Vauxhall. Only Leyland-Triumph seems to have the models and the management to take advantage of the situation, and a government inspired merger between Leyland and BMC is beginning to seem increasingly possible. Certainly it is known that both the Ministry of Technology and the Industrial Reorganization Corporation have been trying to push in that direction, so far without success.

Perhaps this is why BMC is often heard plaintively to say that it is no more than the government's economic football, a phrase once reserved for the private steel companies. This is hardly fair—nobody has yet suggested that BMC should be nationalized, though it could conveniently be done without even a change of name. It is certainly true, however, that government pressure has damaged the industry by forcing it to expand in areas away from the centres of distribution. For all the fine phrases about the motor industry in Scotland—even repeated this week by an American, the new chief executive of Rootes—there is little doubt within the industry that the Scottish experiment has been a failure.

NEWS AND VIEWS

Is Ethology Respectable?

PROFESSOR W. H. THORPE makes a brave claim on behalf of ethology in his remarkable review of two books on animal behaviour (this issue, page 17) and everybody will respect him for it. And he is right, of course, to plead for a more serious recognition of the potentiality of a serious pursuit of studies in ethology. The field has been too neglected for too long. A part of the trouble is lack of money, for studies of this kind can be expensive and biologists have been slow to follow the physicists in forming a sufficiently ambitious conception of the scale on which studies of this kind should be conducted if they are to be profitable. And then, of course, it is often more convenient to stay at home in some laboratory than stump the Serengetti or some other outlandish place in search of suitable experimental conditions. It is, however, probable that the most serious of the problems to have beset the ethologists are intellectual in character. present, at least, the concepts are necessarily ill defined. if only because their formation entails the choosing of names for complicated patterns of behaviour which can only be defined descriptively. In the circumstances it is no wonder that the ethologists have often been hard pressed to distinguish between what they do and what used to be known as natural history. In this, they have not always been successful.

The problems of the ethologists are typified by the continuing dispute about the part played by Dr K. Lorenz in the foundation of the subject. To ethologists, Lorenz is a kind of Freud. Professor Thorpe, for example, after tracing the origins of the subject back to Pavlov and Sherrington, goes on to say that the subject was "fragmentary and uncoordinated until Konrad Lorenz, inspired primarily by Heinroth, succeeded in welding these concepts together so as to form a thorough-going theory of animal behaviour". It is only fair to admit that Lorenz is not always held in such high regard. Only a few months ago Sir Solly Zuckerman was taking Lorenz to task for sloppiness —and worse—in the book On Aggression (see Nature, 212, 563; 1966), and it is plainly especially difficult for ethologists to turn the other cheek to the charge of inaccurate observation. But it is equally hard for them to know what to make of the charge against Lorenz that his formation of concepts may have been clouded by a kind of wishful thinking. Those who claim that Lorenz is sometimes willing to play to the gallery of the animal lovers may have more than suspicion on their side. But may it not be that the critics and the devotees are both correct? If the ethologists find Lorenz's concepts helpful, does it matter if they are not based on the most rigorous arguments and the most unshakable experimental evidence? It would then be necessary to condemn all the other distinguished people who have been led to splendid theories by shaky arguments. There is a sense in which the proof of the pudding is in the eating. This is how Lorenz—and the ethologists as a whole—will eventually have to make their way.

This is perhaps the connexion in which it is most sobering to see it put in black and white that ethology so compels a comparative attitude of mind that it has already broadened the horizons of psychology and is about to do the same for social psychology, psychopathology and perhaps even sociology as well. In some sense, of course, this must be true, but Professor Thorpe's avowal is evidently not intended as a trivial self-justifying truth, so that the question is to know to what extent ethology will transform the social sciences, and in what ways. For one thing, there are some obvious pitfalls to be avoided. It does not, for example, follow that because rats kept densely packed in cages develop signs of stress, that people who live in cities are more likely to become neurotic than those who happen to live in the countryside. (To say this does not of course imply that seriously minded ethologists would make such an unsubstantiated comparison.) One obvious difficulty is that people seem to be exceedingly complicated, either because they are or because human observers tend to be quite well informed about their behaviour. Another is that there seems to be no obvious way of bringing about a reconciliation between the ethologists and the body of people who have done most self-consciously to describe and understand the intricacies of human behaviour—the psycho-analysts and especially the Freudians. Whatever the rights and wrongs of that dispute, it is wrong just to ignore these men and women. None of this implies in any sense that a proper study of what is called ethology would fail to illuminate in several ways important human problems, and it is entirely right and proper that the enthusiasts should think there is a great deal to be done. Dispassionate observers will be forgiven for putting some eggs in other baskets.

Chronology of Magnetic Reversals

THERE is a certain monumental quality about the geomagnetic survey of the lavas of Eastern Iceland reported on page 25 of this issue. Although the long succession of overlapping lava flows in Iceland has played an important part in the development of rock magnetism in the past fifteen years, the study which has now been carried out is at once more detailed and more comprehensive than most others. Altogether there are some 900 separate lava flows lying on top of each other and these have been sampled at a score of places by cores drilled to the underlying basalt. The direction of magnetization of more than 2,000 samples representative of individual lava flows has been determined. Perhaps the most valuable of the prizes to be won by this activity is an extension of the chronology of the sequence of magnetic field reversals from a few million years to an interval of time which spans the past twenty million years. Iceland is exceptionally well suited to such an enterprise because of its close geological relationship with the mid-Atlantic Ridge.

So far as can be told, chronology for the sequence of reversals of the Earth's magnetic field obtained from Eastern Iceland agrees well with other studies which span a shorter interval of time. Precision in this kind of work is possible only when direct measurements can be made of the age of rocks found to be polarized in a direction opposite to that of the contemporary magnetic field of the Earth. Potassium-argon dating has been of crucial importance in this respect. A year ago, Doell and Dalrymple were able, for example, to fix the age of a sequence of volcanic rocks in New Mexico laid down between 700,000 and one million years ago, which placed the most recent reversal of the Earth's magnetic field at 700,000 years ago. The same measurements would suggest that that period of reversed magnetism was comparatively short lived-100,000 years or so. It seems as if the youngest of the lavas in the sequence from Eastern Iceland, corresponding as it does to a period of normal magnetization, coincides either with the period of normal magnetization just this side of a million years ago or that immediately before it. It is, however, more striking that the long sequence of sixty changes of polarity now identified in Iceland agrees both in character androughly-in chronology with the sequence of magnetic reversals which appears to be fossilized in the igneous rocks spreading outwards from the ocean ridges. On the assumption that the rate of spreading of the ocean floor is a centimetre a year or thereabouts, the rocks 100 kilometres each side of an ocean ridge span a total of ten million years. As Dagley and his collaborators point out, it is a pleasing feature of their work that 32 reversals of the Earth's magnetic field ago, they find a long period of normal magnetization which coincides with such a one already reported from studies of the ocean floor near the East Pacific Rise. Plainly there is at least a possibility that further work along these lines, and the patient correlation of measurements with rocks which can be dated easily and those whose ages must be inferred from assumptions about the rate of spreading of the ocean floor, will yield such a detailed picture of the pattern of reversals in the past 20 million years for the Earth's magnetism to be a rapid and an important means of dating all kinds of the Earth's physical phenomena. This, no doubt, is a goal which will be vigorously pursued.

One particularly interesting feature of the results of the survey in Iceland is that there appear to have been 73 lava flows whose directions of magnetization were anomalous and that at least 55 of these are unambiguously intermediate—magnetized neither in the normal direction nor the opposite direction. The fact that such a high proportion—five per cent or so—of the lava flows examined turn out to have anomalous polarity is itself a proof of how conspicuous a part of the history of the last twenty million years have been these processes of field reversal. With such a large number of examples with which to work, it seems fair to point out, as Dagley and his collaborators do, that this may be evidence for a comparatively gradual process of reversal. Moreover, it may indicate that in the course of a reversal, there is a swinging round of the direction of the Earth's magnetic field and not simply a diminution of its intensity and then an increase in the opposite direction. Whether evidence of the kind which has now been collected in Iceland will in itself be sufficient to decide unambiguously between several possibilities in this field remains to be seen, but there can be no doubt that a long sequence of measurements like those which have now been obtained will be of the greatest value in suggesting which hypotheses it will be most profitable to test.

What Controls Chromosomes?

THE chromosomes of wheat, like those of *Drosophila*, have been an extraordinarily fruitful field of study. The reconstruction of the evolution of modern cereals in prehistory from the cytogenetical evidence is, of course, a classic; the Neolithic peoples of the Mediterranean were not geneticists, but it is clear that they were plant breeders with a vengeance. But the chromosomes of

wheat have also been an important object study in the understanding of the functioning of chromosomes as such. So much is clear, yet again, from the report by Riley and Chapman (page 60, this issue) of the role of a particular chromosome of common wheat (*Triticum aestivum*) in the genetic control of the behaviour of chromosomes during the meiosis. The point at issue is

that of knowing precisely how it is arranged that, in all divisions which halve the number of chromosomes as a prelude to sexual reproduction, there should be a regular pairing and segregation of homologous chromosomes. What Chapman and Riley have done is to show how one chromosome can set an orderly stamp on the behaviour of others.

The usefulness of common wheat in work of this kind depends on the ease with which it is possible to obtain plants with sets of chromosomes which differ in controlled and known ways from the normal set of forty-two. This, no doubt, is itself a consequence of the way in which the set of forty-two is derived, in the evolution of modern wheat, from two successive hybridizations of closely related species of more primitive plants, the result of which has been to lump together three sets of seven pairs of chromosomes. In practice, the different sets of chromosomes—the three genomes are conventionally named A, B and D—are distinctive enough to ensure that the polyploid behaves as a diploid. In other words, one chromosome will always pair with its homologue from the same genome and not with the homoeologous chromosomes from the other two genomes.

Riley and Chapman are particularly concerned, in this most recent work, with that pair of chromosomes in the genome B which is known as 5B. These chromosomes are markedly asymmetrical, with the long arm much longer than the short. It has been known for some years that this pair of chromosomes is necessary for normal pairing or synapsis during meiosis. Without 5B, homoeologous pairing is rife—with only one of the pair of chromosomes in a plant, homologous pairing becomes the rule. Extra 5B chromosomes make no difference, but extra pieces of the chromosomes consisting of the long arms alone bring about abnormalities of pairing. So much is known. By growing plants with an excess or sometimes even a deficiency of the long arm, with and without the short, Riley and Chapman have shown that the long and short arms have antagonistic effects on the orderliness of pairing at meiosis. They follow Feldman in the view that the 5B chromosome functions by influencing the spatial distribution of chromosomes before synapsis, and in particular that the long arm ensures that the members of pairs of homologues are closer to each other than to the corresponding homoeologous chromosomes. But

Water into Steel

EVERYBODY knows that steel makers are among the most prolific users of water, but it now seems that they are also enormously variable in this respect. A survey of the steel industry in the United States which has been carried out by the United States Geological Survey shows that some steel companies use very large amounts of water and that others are, by comparison, much more sparing in the use they make of it. The biggest variation in the use of water seems to arise from differences between steel manufacturing plants in the practice of re-using water. The results of this survey, based on the inspection of 16 ore production plants and

an excess of the long arm will make all distances too great, so that the efficiency of pairing is impaired. Only the short arm of 5B can counteract the effects of an excess of the long arm, again by influencing the distribution and orientation of all the chromosomes.

By themselves, these findings will be an important addition to what is already known about the influence of particular chromosomes in common wheat. Previous studies have, for example, shown that the long arm of the 5D chromosome is necessary if homologous chromosomes are to pair normally at low temperatures. The long arm of the 5A chromosome has a similar though less pronounced effect, and the third chromosome from each of the three genomes is also necessary for regular pairing. Given the ease with which it is apparently now possible to add or subtract pieces of particular chromosomes to or from the genetic constitution of wheat, there is every prospect of a much fuller understanding of how each portion plays its part. It is more difficult to see precisely how these and other results will be interpreted in terms of molecular biology. If the long and short arms of the 5B chromosome are somehow involved in positioning of the chromosomes of wheat as a prelude to cell division, how precisely is this effected?

Is there some molecule manufactured by 5B which can attach itself or otherwise influence all the other chromosomes? Are there—an unlikely possibility—long range forces which do the job? Or is there some underlying structure in the medium within which the chromosomes lie which can be influenced by 5B? As yet these and other possibilities remain but speculations

Wheat cytogenetics also has its practical side. It has, for example, been possible to introduce resistance from closely related species by interfering with the activity of the long arm of 5B so that hybrids can undergo normal meiosis, when genes for resistance may be incorporated into the wheat by the recombination of genetic material which occurs after pairing. What has now been discovered about the short arm of 5B may be exploited to increase homoeologous pairing. The practical consequences may be much delayed. New strains take decades to reach the farms. But if the immediate interest of wheat cytogenetics is theoretical, its more distant influence in agriculture may be more significant.

29 manufacturing installations during 1957 and 1958, are described in Water-Supply Paper 1330-H of the US Geological Survey (to be had from the US Government Printing Office). It is not entirely clear why it should have taken the survey the best part of a decade to produce this analysis.

Estimates of water consumption in steel manufacture in the past have been exceedingly variable among themselves. More than a decade ago, however, the Senate Select Committee on Water Resources is said by the Geological Survey to have reported that the manufacture of a ton of steel consumes 31,842 US gallons of

water. The average consumption of the plants covered in the survey works out at 34,000 gallons per ton of ingot steel. The production of iron ore from mines in the United States involved the consumption of 5,900 gallons for each ton of concentrate.

Most of the water used in steel manufacture is used for cooling, which is why great savings are possible. Among the integrated steel plants (which include blast furnaces, steel making furnaces and possibly processing plants as well) the intake of water seems to have ranged from 1,340 gallons per ton to 66,300 gallons a ton, with a median of 24,300 gallons a ton. Variations in the amounts of water actually employed in the manufacture of a ton of steel seem to have ranged from 11,200 gallons to 100,000 gallons, with a median of 33,200 gallons (and an average of 39,500 gallons). But actual consumption—the difference between intake and output—works out at merely 1.8 per cent of the intake. The most prolific users of water among the integrated steel plants used irrevocably 2,010 gallons of water for each ton of steel, compared with the average of 491 gallons per ton. More than half of this water (263 gallons per ton) was lost by evaporation from cooling systems, and 150 gallons of water per ton of steel was used to keep the boilers supplied.

Collagen Discussion Group

ROUGHLY 60 people took part in the second meeting of the Collagen Discussion Group which took place in Manchester on September 25. There were three communications under the general heading "The Nature of Soluble and Insoluble Collagens", in the first of which Professor D. S. Jackson outlined the methods for the extraction of soluble tropocollagens from tissues and showed why the various types obtained depended on the conditions.

Dr F. S. Steven dealt with the insoluble collagen remaining after removal of the soluble varieties. This material can be rendered dispersible in acetic acid by treatment with crude bacterial α -amylase to an extent which varies with species and type of tissues. By raising the pH of the acetic acid dispersion, a fibrous mass called "polymeric collagen" is precipitated. EDTA and other metal chelating agents are as effective as α -amylase, and both types of pretreatment produce polymeric collagens identical under the electron microscope and with respect to aminoacid composition (apart from ornithine content), but EDTA gives a product containing rather more hexose and hexosamine than that derived from α -amylase pre-treatment.

It was suggested that polymeric collagen consists of tropocollagen molecules polymerized by intermolecular covalent cross-linkages, not necessarily similar in chemical structure to the established interchain cross-linkages of tropocollagen. In mature connected tissues, the polymeric collagen fibrils are probably bound together by an intercibrilon substance to form the collagen fibre. A polymeric cibrilon could be released from the fibre by the enzymes of the crude bacterial α-amylase preparation or by chelating agents.

Professor Jackson summarized in his contribution existing knowledge aimed at visualizing the processes in the formation and deposition of collagen fibres in living tissue. The first stage would involve cross-linking of tropocollagen molecules to form microfibrils. These might then be further associated by interaction with mucoproteins to form fibrils of large diameter. Interaction of these with mucopolysaccharides would complete the process. The noncollagenous components might also determine the structure and function of the different connected tissues.

The contribution by Dr R. Reed and Mr S. J. Kennelly dealt with a comparatively new technique for preparing specimens in such a way that alterations due to mechanical distortion and chemical action are minimized. The specimen from the skin is rapidly cooled to the temperature of liquid nitrogen and then cut to give a plain surface. Evaporation of the ice crystals leaves an "etched" surface, a replica of which is prepared for electron microscopy. This method was used to study changes after treatment of the skin with soluble collagen extractants and to study prolonged treatment with alkali which converts the insoluble to the so-called "eu-collagen" which is then soluble in acidic solutions. Alkali was shown to disorganize the collagen fibres and eventually convert them to a mass of fine filaments of widely varying lengths, while in specimens treated with acid they were dispersed and shortened. This method of freeze etching showed promise in this type of study.

More about Haemoglobin

from our Molecular Biology Correspondent

EVER since the determination of the crystal structure of the haemoglobin molecule, a final explanation of its mechanism has appeared to be just over the next hill. Some interesting new experimental data are now described in four papers by Guidotti (*J. Biol. Chem.*, **242**, 3673, 5919: 1967). He has studied the dissociationassociation equilibrium between sub-units in solution in deoxyhaemoglobin and liganded haemoglobins and on the basis of these results has shown that the association state of partially liganded haemoglobin (of which the most important example is partly oxygenated haemoglobin) is compatible only with the existence of mixed tetramers of the type $(\alpha\beta)(\alpha*\beta*)$ where the asterisk denotes a liganded chain. This idea has been previously expressed by the Benesches and their associates, and it is satisfactory that Guidotti's results provide such strong support. The conclusion is general and will apply to any situation in which hybrid tetramers consisting of two different dimers can be formed.

This central hypothesis leads to a complete description of the oxygenation mechanism in favour of which Guidotti has assembled a considerable body of evidence. The dimer $(\alpha\beta)$ is envisaged as the effective functional unit of the molecule in that α and β will both exist in the same reactivity state. Oxygenation will then begin with an essentially simultaneous reaction of the two haems of one as dimer. Thus at any one time, a solution of haemoglobin in the presence of oxygen will contain five species, three tetrameric $(\alpha_2\beta_2, \alpha_2^*\beta_2^*)$ and $\alpha\beta\alpha^*\beta^*$ and two dimeric $(\alpha\beta)$ and $\alpha^*\beta^*$. The relative $\alpha\beta\alpha^*\beta^*$) and two dimeric ($\alpha\beta$ and $\alpha^*\beta^*$). concentrations of the dimers and tetramers will depend on the total protein concentration, and an analytical version of the Hill equation is developed in terms of concentration, association constants for dimerization of the deoxy- and oxy- forms and intrinsic binding constants for oxygen. Not only does this equation describe the observed oxygen uptake curves under normal conditions, but it also predicts the hitherto inexplicable high value of the Hill constant (reflecting high haem-haem interaction) under conditions where the haemoglobin is dissociated. All the parameters in the equation can be evaluated by independent experiments, and the fit must therefore be seen as a strong argument in favour of the hypothesis.

The scheme demands differences in conformation of any chain when it combines with the ligand, and from dissociation behaviour and reactivity of sulphydryl groups Guidotti shows that there appear to be conformational differences between the deoxygenated dimer $\alpha\beta$, the oxygenated dimer $\alpha^*\beta^*$, and the former in its combination with the latter, i.e., as $\alpha\beta\alpha^*\beta^*$. Guidotti expresses the hope that X-ray analysis of oxy- and deoxyhaemoglobins at high resolution will reveal conformational differences, no matter how small, within the chains.

So far this hope has not been too well borne out. The latest X-ray study from Perutz's laboratory (Muirhead et al., J. Mol. Biol., 28, 117; 1967) reports the structure of human deoxyhaemoglobin at 5.5 Å resolution. Detailed comparison is available only with horse oxyhaemoglobin, but it is clear that in terms of tertiary structure the two proteins are closely similar in all respects, including the relationship between the haem group and the peptide chain. The change in the relative orientation of the sub-units, which amounts to a considerable rotation, has been precisely characterized, and changes in the contacts between sub-units are noted. At only two points, one in the a and the other in the β chain, are slight conformational differences observed, though these are interpreted with caution. How such small differences of conformation might be capable of accounting for the very considerable chemical differences observed by Guidotti remains in doubt. The possibility that these reactions are governed by ionization differences which do not significantly affect the conformation must be considered. Guidotti's mechanism of ligand binding at this stage, however, still carries considerable conviction.

Chloroplast DNA

from our Cell Biology Correspondent

EVER since the discovery that mitochondria and chloroplasts contain DNA, the enzymes for DNA replication and transcription and distinct machinery for synthesizing protein, there has been speculation that these organelles evolved from symbiotic bacteria and that they have retained at least partial genetic autonomy. If this is so, it is obviously important to discover just how much genetic autonomy they have. Which proteins in the plastids are coded for by local DNA and which by nuclear DNA? In two papers in Biochem. Biophys. Res. Comm. (28, 598 and 604; 1967), Smillie and his collaborators report on the way in which the DNA in the chloroplasts of Euglena gracilis serves as a source of information.

Not surprisingly, given the evidence that plastid ribosomal RNA is distinct from cytoplasmic ribosomal RNA, Steele-Scott and Smillie find that ³²P-labelled ribosomal RNA from *Euglena* chloroplasts hybridizes with chloroplast DNA but that the total ribosomal RNA from cells grown in the dark, which lack well

developed chloroplasts, fails to hybridize. They interpret this as showing that the chloroplast DNA rather than the nuclear DNA codes for chloroplast ribosomal RNA. A rough estimate indicates that each chloroplast has of the order of 20–45 ribosomal RNA cistrons and presumably the chloroplast ribosomal proteins are also coded for by the DNA of the organelles.

To test whether photosynthetic enzymes either in the stroma or bound to lamellae are synthesized in the chloroplast and, therefore, by implication, whether they are coded for by the chloroplast DNA, Smillie et al. had to use a much more indirect approach. They reasoned that because protein synthesis in plastids and bacteria but not in plant cytoplasm is inhibited by chloramphenicol, whereas cycloheximide inhibits protein synthesis in plant cytoplasm but not in bacteria, enzymes made in chloroplasts should be inhibited by chloramphenical but not by cycloheximide. The inhibitors were fed to Euglena differentiating chloroplasts and the cell extracts were assayed for three bound proteins of the electron transfer system (ferredoxin-NADP-reductase, cytochrome-552 and cytochrome-561) and for two stromal enzymes (ribulose-1, 5-bisphosphate carboxylase and NADP-glyceraldehyde-3-phosphate dehydrogenase). Chloramphenicol, but not cycloheximide, inhibited the synthesis of the stromal enzymes, which must therefore be supposed to be synthesized in the chloroplasts. Synthesis of the electron transfer proteins was also inhibited by chloramphenical, and this implicates the chloroplast ribosomes as the site of synthesis. In this case, however, the result is less clear cut because cycloheximide also had some inhibitory effect. Smillie et al. suggest that this inhibition by cycloheximide may be caused by some secondary indirect effect of the inhibitor on the synthesis of some chloroplast protein in the cytoplasm.

Thus it appears that enzymes involved in photosynthetic reduction of carbon dioxide and electron transport in chloroplasts are made within the organelle and probably coded for by the chloroplast DNA. By contrast, soluble mitochondrial enzymes involved in the oxidation of carbon compounds to carbon dioxide (Roodyn et al., 1962; Clark-Waller and Linnare, 1967) and the mitochondrial cytochrome C (Beattie et al., 1966; Huang et al., 1966) are synthesized outside the mitochondria. These results suggest that a wider range of proteins is synthesized within chloroplasts than in mitochondria and therefore that chloroplasts have greater genetic autonomy than mitochondria.

Chromatography and Spectroscopy

from G. R. Primavesi

Almost from the beginning of gas chromatography, innumerable chromatographers and spectroscopists have collaborated in establishing the purity of standards and in identifying unknown components, but the first joint meeting of the Gas Chromatography and Infrared Discussion Groups of the Institute of Petroleum was held at Loughborough University of Technology on September 29.

A. R. Philpotts introduced the discussion with a quantitative estimate of the natural and technical limits of present techniques. Assuming that weak bands are just to be detected and that the whole of a sample can be put at the focus of an ordinary spectro-

meter, one micromole is about the smallest sample size. Various instrumental devices and tricks can sometimes improve this by one or two orders of magnitude and, in favourable cases, strong absorption bands can improve it considerably further, but such improvements tend to be costly and time-consuming. The small mass of component in a gas chromatographic peak makes trapping and transfer as a liquid extremely difficult. If the component is not trapped, the dilution is usually such that examination requires an impossibly long vapour cell. Multi-reflexion and light-pipe cells bring their own problems and need careful design to give any marked improvement. A combined infrared cell and trapping system was described by J. Tadayon. This is made entirely of silver chloride or bromide in which the component condensed by cooling is centrifuged into the cell and examined directly without special condensing optics. These devices are a real advance towards solving the transfer problem.

At the conference, P. A. Wilks described an attenuated total reflexion cell with a cold spot for trapping and examining liquid samples. There was considerable discussion on the effectiveness of this type of cell with the small quantities involved. He also described light-pipe gas cells which, however, require a considerable partial pressure of component to approach the postulated micromole minimum of sample. The use of a simple light-pipe cell in conjunction with a modified spectrometer and a standard gas chromatograph was described by H. A. Willis. A scanning cycle of 63 seconds makes it possible to examine nearly all peaks in a mixture in only one chromatographic run. Fairly high concentrations of components, with at least medium absorption bands, are, however, required.

A commercially available spectrometer was described by S. G. Perry using filters for dispersion with a 5 or 12.5 second scanning time. He concluded that this time was not really short enough and that the spectra obtained had important gaps and were usually too weak. The apparatus did, however, permit immediate comparison of a peak with a standard. D. Welti described a trapping method using a short length of packed column. This method is not new but has not been thoroughly explored. Welti eluted from the trap into special vapour cells and achieved a concentration of the component vapour greater than the original peak. He also described a technique, developed in Holland, which transfers material from a trapping column to a very small potassium bromide disk.

In the general discussion it appeared that nobody was satisfied with the present state of the art. The plea of the spectroscopists for increased concentration of sample may well be met by studying trapping techniques, although significantly increased mass may not be possible. The chromatographers want increased spectroscopic sensitivity (one, two or even five orders of magnitude), but this appears to be unattainable without some unexpected revolution in spectroscopic technique.

European Marine Biology

from a Correspondent

THE European Symposia on Marine Biology were begun in 1966 when what had been a series of German symposia was changed to one representing all European

countries. The object is to bring together, with as little formality as possible, workers in all branches of marine biology. Last year at Heligoland it became quite evident that there was a demand for such meetings, and the Committee for European Marine Biology Symposia (CEMBS) was set up to ensure continuity and to preserve the original character of the meetings. Each is held, by invitation, at a marine laboratory and may be sponsored by any organization. The committee tries to ensure that the venue changes from one year to the next. Once the allocation has been made, the choice of topics and all further organization is left to the sponsoring body. The new organization has been reorganized by the International Union of Biological Organizations. The president of the committee is Dr A. Barnes, Millport, Scotland.

The Second Symposium was held at the end of August at the Biological Station of the University of Bergen, Espegrend, and organized by Professor H. Brattström. The proceedings were opened by the rector of the university, Professor Hakon Mosby, himself a distinguished worker in physical oceanography. The formal papers were organized round a single broad topic—the importance of water movements in marine ecology. Possibly because the effects of water movements are so easily observed on the shore, a large number of the thirty-six papers were given over to littoral ecology. To begin with, Dr J. R. Lewis summarized the effect of water movements on the distribution of littoral organisms, and Dr T. Carstens dealt with the physics of the interaction of moving waves with solid objects. It soon became evident that the measurement of "exposure" presents major problems and there was vigorous discussion as to what can, and should, be measured and even whether the attempt is worthwhile. Even so, various attempts to measure water movement on both exposed coasts and in sheltered waters were described and an apparatus for simultaneously measuring several parameters of the littoral environment was demonstrated. Papers on the effect of water movement on the distribution and behaviour of a wide variety of organisms-bacteria, algae, and molluscs-were all discussed. The absence of physiologically orientated papers on the behaviour of marine organisms in relation to water flow seems to indicate that much more experimental work needs to be done in that field.

A second group of papers dealt with the relationship between water movements and the local and regional distribution of a variety of organismslargely planktonic but even including the giant squid. Some considered the factors in a restricted body of water, such as a tidal estuary on the western Baltic. while others dealt with wider areas-British and Canadian coastal waters, the Arabian Sea, Japan and Okhotsk Sea, the Adriatic and the Southern Oceans and were essentially biogeographical in character, the results being largely based on plankton collections taken during what may be termed "routine" surveys. Once again it seemed to many that definitive answers to many of the interesting and important problems raised as a result of the analysis of such data will only be obtained by a more experimental approach.

The Third European Symposium will be held at Arcachon, September 25–29, 1968, in the Institut de Biologie Marine of the University of Bordeaux

through the invitation of Professor R. Weill.

Industrial Research Associations in Britain

by C. J. ARLIDGE

Secretary, Committee of Directors of Research Associations The OECD has now published a study of industrial cooperative research in Britain (OECD, 17s. 6d.). The report has been prepared by Dr A. B. Hammond, Mr S. G. Attenborough and Mr G. A. Ingram.

Dr Hammond begins by pointing out that when the British Government laid aside £1 million in 1917 to finance the Department of Scientific and Industrial Research, it also said "The independence and initiative of the British manufacturer had contributed largely before 1917 to his success" but "after the war he will need all possible assistance in undertaking and developing research work as a means of enlarging his output and improving its quality. But if the help is to be effective it must increase the manufacturer's independence and initiative."

With the publication fifty years later of this comprehensive historical study by three members of the DSIR team most closely connected for many years with the evolution of a modern look in the British industrial research associations, it is possible to make a critical analysis. Was the legislation in 1917 well conceived? Is it still appropriate to a society more dependent on manufacturing industry than the 1917 legislators could possibly have imagined?

If the legislation was truly well conceived, then one must be puzzled by the relatively small growth in the total investment in the cooperative industrial research associations, from £1 million in 1917 to about £14 million today (£16 million if the non-grant aided research associations are included). To some extent, this question is answered by Appendix III of the report which lists the twenty-two industries which tried but failed to run their industrial research association laboratories as independent units. Eight of these were forced to merge with other more successful cousins (in two cases with the laboratories of nationalized industries). Only one has been continued as a cooperative research venture without grant aid. The rest were forced to close down temporarily or permanently.

The majority of research associations admit that their work is too little known. Active steps have been taken by at least a dozen of the laboratories to correct this omission, and wherever open publication of their work is practicable and permissible this is being encouraged. There is little doubt that this, and the staff career pattern activities described in the recently published OECD document, will enhance the opportunities for recruitment of larger numbers of well-qualified young people.

Of course there have been failures. It would be more surprising if there were not. But the cumulative advances in the use of the original legislation by different industries are incredibly extensive. From the adoption by the Production Engineering Research Association of a substantially sponsored research programme, a policy being adopted now by at least eight or nine other industrial associations, to the integrating and coordinating bank for research and information (rather than providing its own central research laboratory for the industry) instituted this year by the Construction Industry Research and Information Association, the pattern is changing so rapidly that Dr Hammond and his colleagues may consider themselves fortunate that their study was completed four years ago. If they started it now it is unlikely that they would ever have time to finish it.

If we subject the British industrial research associations

to a close examination and consider them in the light of European experience with cooperative research we find three encouraging signs:

- (i) Most British research associations have responded rapidly to the need to make sponsored research complementary to their cooperative research programme. To my knowledge no examination has been made of the reason for this rapid change in policy although it could be due to the considerable increase in American investment in Britain since the war, with the corresponding changes in industrial attitudes.
- (ii) On the international front, British research associations match their opposite numbers in France, Germany and Austria in the recognition that the best research is run on international lines.
- (iii) The industrial research associations whose work is demonstrably used to commercial advantage by their industries are also those with soundly based basic research programmes.

The last of these points seems to me to be the one in most urgent need of examination. The latest research and development statistics for 1964-65 show that the universities, which are believed to be too remote from industry for the effective utilization of their research, are now spending £4 million on applied research and £35 million on basic research; while the grant-aided research associations are spending a paltry £9 million on applied research and nothing at all on basic research. The zero in the basic research column is probably an error, but the relative proportions are interesting. I am tempted to suggest that £20 million for applied research in research associations and £4 million for basic research would be a good working minimum income for the present number of grant-aided industrial research associations. This could indeed be considered a good minimum figure from which to bargain with European industry in our attempts to join the Common Market.

One may ask, however, whether the time is not ripe for the introduction of fresh legislation which would put the laboratories of the industrial research associations on a similar footing to those of the universities—that is receiving Government revenue from the Treasury. Consider the case of the National Institute for Social and Economic Research. This Institute operates in a manner closely resembling the cooperative industrial research associations but receives a grant for its economic studies direct from the Treasury.

In order to assure the Treasury, however, that this form of investment in industrial research would be a sound one, it would certainly be necessary to constitute throughout the network of research associations a strategic policy of management integration with industry. Any scheme designed to cover this requirement would need to be comparable with those already in operation for the large science-based companies. In my view, once a scheme of this type had been established and linked to companies in membership of the research associations, grants direct from the Treasury to industrial research associations on a scale very much larger than that at present envisaged would be a very sound investment.

Zoology and Behavioural Sciences

by W. H. THORPE Why study animal behaviour? In what follows the author argues that this is—or should be—the foundation of a proper understanding and use of the social sciences. The argument is based on two books published recently—"Animal Behaviour" by Robert A. Hinde (McGraw-Hill, 84s.) and "Mechanisms of Animal Behaviour" by Peter Marler and William J. Hamilton (John Wiley, 113s.).

THE boundaries between the four behavioural sciences, physiology, psychology, ethology and sociology, are ill defined. It is true that the central aims of each science are different, so that the emphasis which each makes is characteristic. But as the separate sciences develop, the more they come to overlap both in techniques and in material. Sociology, the youngest of the four, is still in many ways in an embryonic state and tends to be closely restricted to its primary aim of elucidating the structure of human social systems. It is therefore very closely related on one side to anthropology, ethnology and economics, but as yet comparatively little developed in its relations with the first three behavioural sciences. Its connexions here are closest to psychology and ethology and more remotely to physiology. But if sociology is to develop as it should into a true science with an experimental basis, it must develop secure biological roots and become truly comparative. It would seem that it can best do this, at least to begin with, by means of ethology.

First Behaviour Studies

The physiological study of behaviour can be said to have begun with Thomas Willis, the Oxford anatomist who in the early seventeenth century first employed the concept of reflex in a scientific and practical rather than a philosophical manner. This started a chain of development which reached its first flowering with the nineteenth century Russian physiologists, among whom Pavlov may be included although in actual fact none of his work on the nervous system was published until the twentieth century. By itself, the concept of the reflex did not carry the workers of that period very far towards a useful analysis of behaviour, but with Pavlov's concept of conditioning all was changed. For the first time, the reflex theory seemed to be within reach of providing a reasonably satisfactory physiological explanation of animal behaviour. It is hard to exaggerate the importance of the complementary work of Pavlov and Sherrington in the first quarter of the present century in laying the foundations of the physiological approach to behavioural analysis.

The nineteenth century psychologists were solely concerned with human beings. They were so centred on the problems of the human mind, its feelings and emotions, that they could not provide the tools required for the scientific study of animal behaviour until they in turn, towards the end of the century, became imbued with associationism. Such nineteenth century psychological writing as there is on animal behaviour is monumentally

anecdotal and anthropomorphic, and this criticism applies also to at least one physiologist-Romanes. The limitations of the strict conditioned reflex approach to animal behaviour began to be apparent to the naturalists—the field zoologists-almost as soon as it developed; for about this time, zoologists were beginning to be more scientific and more objective about animal behaviour. really as a delayed result of Darwin and in particular of his Expression of the Emotion in Man and Animals (1872). But in the second decade of the present century it was not only the naturalists who became aware of the obvious deficiencies of the existing mechanist-physiological approach to the study of behaviour. Those among the physiclogists and psychologists who were studying the more highly developed perception of animals were equally sceptical, and so it was that Wertheimer1, working on the visual perception of movement, and later his disciples Wolfgang Köhler² and Koffka³, came to propound the concepts and theories which in due course produced the Gestalt psychology. This started a battle with the behaviourists which has waxed and waned as the two sides have changed their position slightly over fifty years, and is far from dead even now.

Coming of Ethology

The process whereby the field naturalists and zoologists came to organize themselves into a logically coherent scientific group was also, of course, slow. Some of the essential contents can be found, for example, in the writings of Lloyd Morgan and, later, Julian Huxley—and it is right to recall the forgotten mid-nineteenth century pioneer Douglas Spalding4. Essential contributions to modern ideas on animal behaviour can be found all appearing at about the same period in the writings of Wallace Craig⁵, H. S. Jennings⁶, Karl Lashley⁷ and C. O. Whitman⁸ in the United States. Equally, if not more, important was Oscar Heinroth's in Germany. But the output of all these workers, so far as theoretical consequences were concerned, was fragmentary and largely uncoordinated until Konrad Lorenz¹⁰⁻¹², inspired primarily by Heinroth, succeeded in welding his concepts together to form a thorough-going theory of animal behaviour. As a result, Lorenz is rightly considered the founder of the new movement. Some of his formulations are now regarded as outmoded and have been subject to strong criticism; but the fact remains that Lorenz was the first to provide a systematic and coherent survey of the field of animal behaviour which found a place for all the outstanding problems and without which the scientific study

of animal behaviour could not have been welded together into a distinct discipline as it has been with the adoption of the term "ethology".

This term has played an important part; it is peculiarly appropriate in that its use in the late eighteenth and early nineteenth centuries covered "the interpretation of character by the study of gesture" and also "the art of Thus it is remarkably apt for denoting the methods of the contemporary zoologist-naturalist student of animal behaviour, concerned as he is with interpreting, understanding and relating, both physiologically and psychologically, the movements, actions and action patterns of animals. Thus, about the same time, two large and complementary sections of the study of animals received new names—ecology and ethology—and thereby became better co-ordinated and greatly stimulated. Here again, of course, the fields overlap; though, just as in the larger divisions of science, the primary objectives are different. The ecologist studies the life and organization of animals primarily as an expression of the environmental influences, both animate and inanimate, to which they are exposed. The ethologist includes many of the same problems in his programme, but considers them chiefly as expressions of the nature and organization of the animal itself.

Understanding Behaviour

In one essential respect the writings of Lashley and Lorenz are very similar. Before them there had been much vague talk about the "internal drive" of the animal. Both Lashley and Lorenz realized independently that instead of trying to study this mysterious drive in its own right, and to utter vague generalities about tension, 'nervous energy" and so forth (which were in any case useless as explanatory concepts and of small value as guides for future research), it was better to describe and analyse the complex and stereotyped action systems themselves. These and their co-ordinating mechanisms were assumed to be the fundamental things, and the conviction was felt by both workers that a study of the mechanisms themselves might eventually throw further light on the problems of drive and motivation which are basic to the study of behaviour in animals or men.

Recently there has been an immense proliferation of ethological study and experiment and a stream of books on the subject. Among these many books are two which provide the occasion for this review, the significance of which cannot be fully appreciated except against a historical background. The first is Animal Behaviour: a synthesis of ethology and comparative psychology, by R. A. Hinde; the second is Mechanisms of Animal Behaviour, by P. Marler and W. J. Hamilton. Professor Hinde's book is more fundamental to the over-riding methodological and theoretical problems which are, in one way or another, the concern of all the behavioural sciences at present. It is an outstanding and highly original contribution to the task of synthesis. The book by Marler and Hamilton, while hardly competing in this particular respect, is, nevertheless, also a fine and timely achievement.

Hinde emphasizes the difference between the attempt to predict behaviour and the attempt to understand it. It is often possible to predict behaviour with fair accuracy without moving to a deeper or more fundamental level of analysis. In fact, prediction of this kind is, of course, what every animal trainer does. To understand the organization of behaviour, hypotheses must be judged not only at the behavioural level but also in terms of their compatibility with hypothesis at a deeper level—for example, a physiological level. Indeed, unless a theoretical system can be related to physiological data, it is unlikely to have wide validity even at the behavioural level.

This leads to a discussion of the virtues and vices of models, and Hinde points out that the virtue of a good

model is that it suggests further questions and tempts us to formulate hypotheses which are experimentally fertile. Although analysis down to a physiological level is always desirable, it is at present very often unattainable. But while "physiologizing" is a long term aim, it is also much more than that; it is a valuable source of information and inspiration to the student of behaviour. A fertile psychology cannot afford to ignore physiological data, which may suggest useful concepts; psychologists or ethologists who deny themselves such data are in danger of neglecting an important source of evidence. Models then, if well and carefully chosen, often facilitate bridge building between ethology and physiology.

Causes and Mechanisms

In his book Hinde makes much use of functional schemata to illustrate definite causal relationships. Though essentially quite abstract, they serve to indicate the job which the physiological machinery must be doing and provide the physiologist with an indication of what he must look for. This is, of course, exactly the objective at which the first formulations of Lorenz were aimed, and no greater justification of the method need be sought than the great success of the Lorenzian theories in energizing and stimulating behaviour study. But because such formulations are abstract, they continually need refinement and translation into the contemporary physiological and ethological terms. In this book, the essential problems brought into focus by the Lorenzian terminology are discussed and illuminated and often immeasurably advanced after three decades.

Often the development has been to break up what were originally considered to be quite simple explanatory ideas into a number of parts which then become amenable to experimental analysis. This is clearly seen in the term "drive", which used to be shared by psychologists and ethologists in previous years. Hinde has shown the dangers of clinging too long to the concept of the theoretical unitary drive system, and one of the great contributions of Hinde's own research and of his book is to show how developments in neuroendocrinology have now made possible an enormously more effective and detailed understanding of many cases which would previously have been merely dubbed as due to "an internal drive". The account of the general effect of the brain-stem reticular system on behaviour and its relation to the concept of general drive and the effects of sensory deprivation is particularly cogent.

The first main section of the book is a masterly summary and exposition of the whole field. The synthetic aspect of the book is especially apparent, in that its examples are drawn from the behaviour of animals in the field and in the laboratory, with physiological advances introduced wherever relevant.

The chapter on the control of movement is particularly valuable for its emphasis, in connexion with feedback control, upon the idea of the concept of target value "or equilibrium position"—terms which are to some extent synonymous with the German "Sollwert" (literally, the "should-be value"). In discussing the control of muscular action, the "Sollwert is regarded as achieved when the lengths of muscle and muscle-spindle bear a certain relation to each other"; and this concept is shown to be of fundamental importance to the whole understanding of those fixed action patterns, so interesting to ethologists because so characteristic of species, which used to be subsumed under the general title of "instinctive".

There is also much of interest in the other large section of the book entitled "The Development of Behaviour". One of the sections of principal importance is that dealing with the development of perceptual abilities, which raises the whole problem of perceptual learning, distance and depth perception, and the effect of lack of visual experience on species ranging from pigeons and rats to chimpanzees and human beings. Topics of this kind are very skilfully

used for building bridges between ethology and physiology on the one side and psychology on the other. Another section of particular concern to psychologists is that on "Displacement and Redirection", in which it is shown how several different types of mechanisms, from behavioural inhibition to "redirection", help to account for the puzzling and intriguing examples of behaviour hitherto often lumped together under the heading "displacement".

It is unfortunate that the work of Hinde and his collaborators13-15 on the behaviour of socially living groups of rhesus monkeys, under carefully controlled mild stress and deprivation, is too recent to have found much place in this book. This work shows how rhesus monkeys living in family groups can be used as experimental surrogates for human beings-especially for the study of such vital problems as the effect on subsequent behaviour of early stress and, specifically, the results of maternal deprivation. It is almost impossible to obtain satisfactory evidence of such effects with man, for the consequences take so long to develop and because the circumstances of life of the human subject are too complex for even reasonably scientific evaluation; and, of course, because it is impossible to carry out experimental analysis with human beings. The impacts of ethological studies of this kind on human paediatrics, social psychology and sociology are only just beginning and are potentially enormous. The book hints at what they may become and should serve to alert human psychologists and particularly those concerned with the development of sociology (which one hopes may become a real science in due course) to the absolute necessity that that science should be adequately and firmly rooted in biology.

Things to Come

Hinde's book is pre-eminent because he deals with all the fundamental theoretical questions of ethology with mature and contemporary understanding of all the disciplines involved—especially endocrinology and neurophysiology. The book is encyclopaedic yet kept within manageable proportions. It follows that it is highly condensed and hence not always easy reading. But among the present and forthcoming generation of research workers it will inevitably be the first choice as a guide and mentor—for it has no real competitor in any language.

The book by Marler and Hamilton is also by any standards first class. It does not show the same fundamental theoretical insight, nor does it attempt a similar critique of theoretical foundations and methodology. But it is, like Hinde's book, comparative, thorough and reliable. In short, many of the encomiums given to Hinde are also applicable to Marler. In some respects it is complementary to Hinde's book. Both range over the whole animal kingdom, but the majority of Hinde's examples are drawn from vertebrates whereas Marler and Hamilton's book is noteworthy for the fine series of examples and illustrations chosen from the invertebrate field of study. It is lavishly illustrated and beautifully produced.

What, then, is the future role of ethology in the last quarter of the twentieth century? Obviously there is still much for it to do in continuation of the integrative activity that it has already displayed during the last thirty years. It is characteristic of ethology that its approach is eclectic. That is to say, just because its subject is the whole animal, it is prepared to use whenever appropriate all types of analysis, all types of theoretical approaches, all types of observational and experimental techniques which it finds contribute toward the prime object—the total understanding of behaviour.

Before anyone can proceed with the scientific analysis of any phenomenon he must first classify it. If the phenomenon is a piece of behaviour, such as a righting reflex, we find that there are broadly, as Hinde shows, three forms of classification available to us—causal, functional and historical. The causal classification

presupposes the question: how does it work? The ultimate answer, therefore, tends to be in terms of physiological mechanisms—mechanisms of perception, neural or hormonal correlation and integration, and ultimately mechanisms involving biochemistry. Functional classification presupposes the question: what is this for? What is the adaptive or survival value of this behaviour? Such questions underlie the division into categories such as threat, courtship, parental behaviour and so on, and classifications of this type correspond to the use of words such as "legs" and "eyes" in morphology. As Hinde points out, functional categories are often used to include behaviour, for example. Historical classification comprises two quite distinct systems: specification according to source and classification according to methods of acquisition.

What Ethology Can Give

Ethologists, having approached the study of behaviour in the first place as zoologists, are particularly attracted by evolutionary explanations, and will start by looking upon similarities in patterns of behaviour such as the modes of cleaning or scratching in birds, similarities which are not obviously necessarily correlated with the specific structure of the forms studied, as expressions of an evolutionary relationship. The classification according to the method of acquisition is also historical, but is concerned more with history of the individual-is the behaviour learned or conditioned, and how? This is the approach that tends to be very characteristic of the psychologist, and much misunderstanding between psychologists and ethologists in the past has been due to failure to see that, though they may be discussing the same subject, the two are in fact asking different questions about it.

Ethology, then, has links on the causal side with physiclogy and, in so far as it asks historical questions, in the sense of being interested in the individual experience of the organism, with comparative psychology. Hinde has a useful passage on this key point. Although classificatory systems are basically independent of each other, "Possibilities of confusion constantly arise". Just because functional and causal categories often overlap, the temptation to confuse them may be severe. This is particularly dangerous when the functional categories are nothing more than descriptive generalizations. Reference to "self preservative" as opposed to "reproductive" instincts, for example, "both confuses functional and causal categories and implies something causally in common between, for example, feeding and preening". Similarly, although activities such as scratching, stretching and shaking can be described as "comfort movements", they have been shown to occur independently of each other. Provided these confusions are strictly avoided, and provided that we are always aware what kind of explanation we are seeking, then I believe the eclectic approach by the ethologist will continue to be of central importance in the future development of the behavioural sciences.

Conceptual muddles which have sometimes beset ethologists are, unfortunately, equally characteristic of other sciences, particularly in their early stages. The great contributions which ethology can make to the other behavioural sciences include just those contributions which zoology has, in the past, made to physiology, anatomy and embryology, which for historical reasons were for long purely concerned with the human being—namely the inculcation of the tremendous importance of being truly comparative. There are innumerable cases in all these disciplines of phenomena impossibly complex and difficult to understand when studied solely at the human level, but which immediately become amenable to attack when studied in some simpler, less highly organized or differently organized, organism. Where would neurophysiology be without the giant fibre? Where would

embryology be without the Echinus egg? Where would genetics be without Phaseolus and Drosophila? It is basically because of its evolutionary outlook that zoology was in a position to broaden the studies of the other disciplines in this way. As I see it, ethology is now providing just this service for the psychologist, saying, in effect, that what seems to be the longest way round may be the shortest way there. Predictions are notoriously risky in science; but I am prepared to forecast that ethology will provide the same kind of release and re-direction for social psychology, psychopathology and perhaps sociology in the not too distant future and will thereby show itself as an important unifying influence. In this process I believe that Hinde's researches and writing, especially this book, will have played a major part.

Wind Erosion in East Yorkshire

by J. RADLEY

Royal Commission on Historical Monuments (England), The White House, Clifton, York

C. SIMMS

The Yorkshire Museum, York

The marked erosion of agricultural land in East Yorkshire by the high winds in the first dry months of 1967 is linked with the formation of deposits by two former glacial lakes. There is, however, a danger that modern farming practice will tend to induce further erosion of this sort in this part of Britain.

In certain parts of East Yorkshire, the inhabitants have long been accustomed to localized wind erosion, in the form of sand- and dust-storms, known as "blowing". This produces temporary sheets of sand on metalled roads, dust in the houses, and creates distinctive solid banks along hedgerows, which act as sand traps. In 1967, however, the erosion which took place was far greater than usual. In what follows we shall define the area affected by blowing and attempt to infer some of the causes and effects on the countryside.

Because the erosion took place in February and March, it was essential quickly to visit the whole of that part of Yorkshire liable to wind erosion before the new growth of crops reduced and to a certain extent obscured the erosion and the associated sand deposits. This area is confined to the land covered by former glaciers and post-glacial lakes which have left glacial sands and gravels on or around the morainic deposits in the Vale of York, and lacustrine sands which were deposited on the margins of post-glacial lakes in the Vales of York and Pickering. Other areas liable to erosion are upland areas devastated by moorland fires¹, but these have been little affected in 1967.

After several hundred miles of driving it became apparent that not all the potential areas of erosion were in fact affected, and that erosion was mostly confined to two large areas.

The principal area is already well known for its tendency to blow, and lies on the east side of the Vale of York. During 1967 it has suffered patches of erosion in a belt from the Humber to the vicinity of Northallerton, an

area 50 miles long and 3-11 miles wide (see Fig. 1).

Blowing took place on "Great Sand Field", Market Weighton (SE.8740 and environs), with lesser areas near North Cave and Londesborough. Towards the north, the next affected area was Everingham Common and Allerthorpe Common, the latter extending towards Suttonupon-Derwent and Barmby Moor, in all more than 10 square miles. At Newton-on-Derwent, the small area of sand around the former village sand pit was blown. Farther west, many fields were eroded on Sandfield, North Duffield and Skipwith Common.

Around York the erosion was confined to the north and east. In New Field, the Common and the former warrens at Dunnington, erosion is estimated to have affected at least 800 acres. In nearly every nearby parish, isolated fields generated small sand blows-for example, near Strensall, High Catton, Skirpenbeck and Buttercrambe.

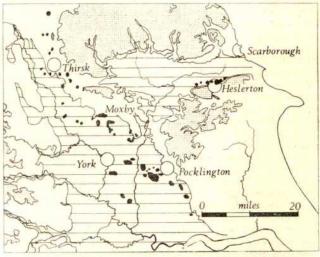

Fig. 1. Areas of blown sand, 1967, represented in black. Stippled areas are over 400 ft., and the horizontal shading covers the areas of glacial Lake Humber (around York) and Lake Pickering (west of Scarborough).

In the parishes of Claxton, Flaxton and Sand Hutton, more than 4 square miles were eroded on the former commons.

Around Sutton-on-the-Forest there were large patches of erosion in the former West Field, on East Moor near what was "The Common Sand Holes" and on Moxby Moor. Smaller areas were found at Tollerton, Myton Moor, Helperby Moor, Husthwaite, Sessay, Thirkleby (by Sand Hill House), Bagby, Carlton Miniott and Sandhutton. Another group of scattered sand blows was found east of Northallerton, as well as near Knayton and East Harsley.

The second and smaller area was located on the south side of the Vale of Pickering in a zone 7 miles long and 1 mile wide, and confined to the parishes of Heslerton, Sherburn, Potter Brompton, Ganton and Willerby.

The Geological Background

Fig. 1 shows the two glacial lakes, the one near Scarborough called Lake Pickering and the other in the Vale of York called Lake Humber. These lakes were formed by the trapping of glacial meltwater in the lowlands by a mass of ice occupying the North Sea basin. The map shows that most of the area which suffered from wind erosion in 1967 lies within the former lakes2. In the Vale of York, the lake stood at about 100 ft. o.D. and randomly deposited lacustrine sands and gravels on a glacial clay and sand gravel floor. These deposits were later partially overlaid, especially near the Humber, by warp clays. As a result, most of the areas liable to wind erosion are slightly raised areas of sand and gravel characterized by very light and fine grained sands, above the lower clays but below the edge of the lake. In the north, the glacial sands and gravels which lie beyond Lake Humber have provided a few limited concentrations of somewhat coarser sand, and these were duly eroded. Both types of sand and gravel are shown in some detail on the relevant Geological Survey sheets3.

Lake Pickering left behind a similar spread of sand and gravel, which in places are concentrated in beach like deposits. These are particularly evident in sand pits (as, for example, at Staxton Corner, TA.024794), where laminated sands can be clearly seen related to a water level at around 250 ft. o.d. The principal beach deposit and the principal area of erosion are on the south side of the Vale of Pickering at its eastern end, presumably because in this region there was more detritus in the water supplied by the Newton Dale and the Forge Valley overflow channels bringing meltwaters from the north.

In post-glacial times, the shoreline deposits were liable to blow, presumably before the natural vegetation blanketed them. Sand was blown eastwards in the vicinity of North and South Cave and Sancton over a distance of more than a mile on to Houghton Moor and Sancton Wold, with similar deposits on the southern side of the Humber.

Causes of the Erosion

January-April 1967 was relatively mild in East Yorkshire, with very little frost and snow. In January the rainfall was 39 per cent of the average, in February, 98 per cent, in March, 77 per cent, and in April, 61 per cent. In combination with temperatures above the average, these dried the surface, lowered the watertable and produced very dry topsoil conditions wherever the soil was exposed by ploughing. Although there were a few brief storms, the period was also characterized—especially in March—by the high frequency of gale force winds, predominantly from the west or south-west⁴.

Wherever the soil had a high fraction of sand, and especially if the sand was fine, it was whipped away to form sand dunes and sand sheets. Elderly people in the Moxby and the Heslerton areas had not experienced as much blowing in their lifetimes. In some cases, the excessive erosion cannot be readily accounted for by changes in physical conditions or in farming practice. In the Hesler-

ton area, however, a comparison of the present landscape with the 6 in. O.S. maps of the area reveals that numerous hedgelines have been grubbed out to permit large scale mechanized arable farming. This has undoubtedly led to increased exposure of the sandy areas to a greater "fetch" of wind, and to increased scouring of the topsoil. A similar origin has been attributed by local farmers to the blowing south of Thirsk and south of Selby.

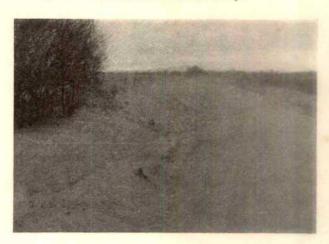

Fig. 2. Sand on the York to Helmsley Road, photographed during a

In the parish of Moxby, there were several areas with small dust-bowl scenes with dust blanketing visibility for more than a mile, but the most spectacular place was Moxby Moor. This is a low, sandy ridge with small hedged fields aligned east to west. One 7 acre field supplied so much airborne material that the York-Helmsley road was blocked at Easter (SE.583663), and the road was only afterwards kept open by stationing a road sweeping vehicle at the spot to sweep back and forth continuously on a 100 yard stretch of road for a week (see Fig. 2). Dunes well over 3 ft. high were visible for several weeks after the erosion had more or less ceased. Down wind from this, on a barley field in the lee of one hedge (Fig. 3), dunes up to 4 ft. high were formed over a distance of 275 yards and a width of more than 15 yards—an estimated minimum of 50,000 cubic feet. There are estimated minimum of 50,000 cubic feet. several derelict marl pits in the area, which suggests that marling was used on the local sands as an early remedy to blowing.

Farther south, small dust clouds were seen for weeks over fields at Full Sutton (SE.754560), at Buttercrambe (SE.715568) and at Claxton (SE.698602), where small

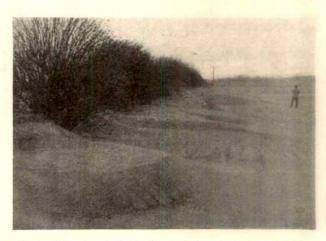

Fig. 3. Dunes forming in the lee of a hedge, photographed during a dust-storm.

R350

rippled sand sheets drifted in field corners and on to roads, but these will have very little long term effect. The large clouds of dust and sand on Sand Hutton Common (SE.6757, 6857) were more impressive; a grey peaty sand was swept into drainage ditches and onto growing winter wheat; in general, however, the fields are so big that the effect of the erosion is mostly a redistribution of the sand. Only a little is removed from the area.

In the Vale of Pickering, the post-glacial beach sands lie at the foot of the Chalk Wolds which are aligned east to west. The yellow brown sandy fields called "The Grits" in Sherburn are sharply distinct from the upland chalky white soils and the carrland peaty black soils beneath them. The agricultural pattern was formerly one of pasture with north-south pine windbreaks and a few arable fields distinguished by the high banks under their hedges indicative of decades of gradual erosion of the sands. The present trend on the sands is towards grain and bigger fields. In 1967, the wind was funnelled down the Vale of Pickering, and at Ganton and Potter Brompton (SE.966770) drifts of more than 3 ft. lined the fences, large patches of growing wheat were bruised and flattened, grass verges were blanketed and small sand sheets drifted across the A.64 road (see Fig. 4). There was no visible erosion at all on the clay soils of the area.

Presumably, the high winds which produced the blowing have affected areas of light sandy soil in other areas. Some

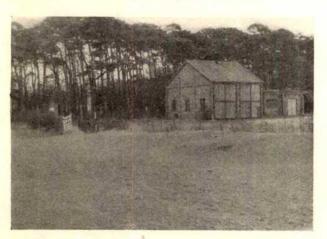

Fig. 4. Near Potter Brompton. Ripple covered dunes on the roadside, with a pine wind-break in the background, photographed during a dust-storm.

has been noticed south of Selby, near Burn and on Camblesforth Common (SE.630278 and vicinity) where it has become more significant in the last few years following the removal of some hedgerows.

Effects

Apart from the temporary dramatic manifestations of dust-storms reaching as high as the tops of electricity pylons, the dunes and the blocked roads and ditches, there are more lasting effects. It is clear from the names used in the area of study that the sandy areas were the parish commons and moors until they were enclosed about 1760-1830. That there has always been a little erosion each year is an accepted part of farm life, but the absence of windbreaks in some areas-for example, around Pocklington and Allerthorpe-coupled with the tendency to grub out hedges is bound to increase the erosion. The problem is aggravated when farmers, as witnessed in the York area, continued to disk their fields at the height of the gales. Perhaps the most significant effect is the loss of the topsoil, not as a mineral layer but as an expensively fertilized and artificially productive substance. Money is in fact being slowly blown away. In some areas the effect on crops already planted was noticeable. Fields around Pocklington planted with carrot seeds had patches of sand removed, seed and all. At Tollerton, sand-blow exposed seed barley before it had germinated and this survived, but winter wheat was battered and broken and even buried in some fields. Probably a return to marling, last practised on a large scale in the Second World War, when 4,000 acres are known to have been treated5, would help to reduce the chances of blowing in some areas, but this is a very expensive operation.

The processes of erosion in Britain are usually slow, continuous and unnoticed, but occasionally, as in 1967, conditions may combine to accelerate erosion which can be visually dramatic and economically serious. If the present trend in farming continues, and if more sandy areas are ploughed and more hedges are grubbed out, it is probable that very careful management will be necessary to minimize blowing and its consequences even under less extreme conditions.

Origin of Low Energy Cosmic Rays from Outside the Solar System

by
G. R. BURBIDGE
W. A. FOWLER
F. HOYLE
Institute of Theoretical Astronomy,
University of Cambridge

The abundances of heavy nuclei in the low energy primary cosmic ray flux can be accounted for by the co-existence of two components, one of which has undergone nuclear spallation reactions. The passage of primary cosmic rays through the ambient gas clouds thought to be associated with quasi-stellar objects is one way in which spallation on a sufficient scale may have occurred.

It is usually considered that cosmic rays have path lengths of 4-5 g.cm⁻². This is consistent with the production in the flux of primary heavy nuclei of LiBeB from CO in a ratio $\sim 1/3$. It is also consistent with the ratio $\sim 1/3$

observed at energies $> \sim 1$ GeV per nucleon for odd to even nuclear charges (z) with $z \ge 10$. Path lengths significantly greater than 5 g.cm⁻² are thought to be ruled out by the low value of the helium isotope ratio He³/He⁴

⇒ 0.25, for longer paths would lead to higher values of this ratio. The data at energies of more than ~1 GeV per nucleon have been reviewed by Webber¹, who remarks, "The value of 4 g.cm⁻² is consistent with our rather crude knowledge of the fragmentation parameters and ideas of the relative absence of odd nuclei in the source regions. Path lengths ≥ 10 g.cm⁻² for the regular diffusion model seem to be incompatible with the presently measured charge distribution".

An unexpectedly small value $\leq 1.4 \times 10^{-3}$ has recently been reported by Comstock, Fan and Simpson² for the ratio F/O at energies $< \sim 100 \, \mathrm{MeV/nucleon}$. These authors have pointed out that this determination casts doubt on the picture described in the previous paragraph, at least as far as low energy cosmic rays are concerned. Bernas et al.3 have measured a cross-section of 28 mbarn for the nuclear reaction $F^{19}(p, pn)F^{18}$ at a incident proton energy of ~ 150 MeV. We expect the same spallation reaction $Ne^{20}(p, pn)Ne^{19}$ to have a similar cross-section, for Ne^{20} has two neutrons outside the closed p shell, as does F^{19} . Thus the fraction of Ne²⁰ converted to Ne¹⁹, and then by $\beta\text{-decay}$ to F19, in a path of 4 g.cm-2 in hydrogen is $\sim 2\cdot 8 \times$ 10^{-26} . $(4/M_{\rm H})$ where $M_{\rm H}$ is the mass of the hydrogen atom. This fraction is ~ 0.07 . With Ne/O $\simeq 1/7$ we have an expected value ~ 0.01 for F/O arising from the spallation of Ne²⁰ alone. Allowance for some production from other nuclei, particularly Mg24, gives a discrepancy between the expected ratio and the observed upper limit equivalent to a factor of about 10.

Several workers (Y. Pal, private communication, and P. H. Fowler, private communication) have sought to escape from this difficulty by assuming a distribution of path lengths p of the form $\exp{(-p/p_0)}dp$ with $p_0 \simeq 5$ g.cm⁻². With this value of p_0 , however, there is still far too great a production of F. It seems to us that a very low value for F/O cannot be obtained unless there are virtually no path lengths of 4-5 g.cm⁻².

We wish to consider a model in which the low energy cosmic rays are a mixture of two components, one which has experienced little or no spallation and one which has experienced spallation corresponding to path lengths as great as 20 g.cm⁻². This model was first proposed by Comstock et al.², who discussed it briefly within the framework of the galactic theory of cosmic ray origin. The first component is necessary if we are to understand He³/He⁴<0.25, while the second component is necessary to account for the observed occurrence of LiBeB. We have the following situation

FIRST COMPONENT	SECOND COMPONENT
$He^3 = 0$	$\mathrm{He^3/He^4} \simeq 1$
LiBeB = 0	LiBeB ≃ (CO) before spallation
$\mathbf{F} = 0$	
He4, C, O without spallatio	n (CO) before spallation $\simeq 0$

If the first component is some two or three times more important in the mixture than the second component, we immediately obtain LiBeB/CO $\simeq 1/3$, He³/He⁴ $\lesssim 0.15$. Where F is concerned, there is none from the first component and comparatively little from the second component. This is because NeMgSi, which are the most important progenitors of F when the path length ~ 5 g.cm⁻², become too heavily attacked by spallation to yield much F at significantly greater path lengths. This point will become clearer from the following argument.

A nuclear species exposed to protons of several hundred MeV can be regarded as continuously affected by spallation according to the equation

$$\frac{\mathrm{d}A}{\mathrm{d}p} \simeq -\frac{A}{50} \tag{1}$$

where the atomic weight A is a function of the path length p (in g.cm⁻²). Equation (1) may be derived in two ways. An incident proton can be considered as having an average cross-section of ~35 mbarn for experiencing scattering by any one of the nucleons within the nucleus, provided A is not too large. The number of nucleons expelled per g.cm⁻² of path is therefore $\sim 3.5 \times 10^{-38}$ A more conventional way of looking at the same problem is to consider the target area mr. $r_0 \simeq 1.2 \times 10^{-13} A^{1/3}$ cm for collision of a proton with the nucleus, giving $\sim 4.5 \times 10^{-26}~A^{2/3}/M_{\rm H}$ collisions per g.cm⁻² of the path. Then, taking the number of nucleons expelled per collision as proportional to the radius of the nucleus in other words, to $A^{1/3}$ —we again obtain an evaporation rate proportional to A. The numerical coefficient is also the same as before, provided the average number of nucleons expelled per collision is close to $A^{1/3}$. Most of the nucleons will be expelled separately or as a particles. (It is important to recognize that this argument would require modification at higher proton energies, for π -meson production raises complications.)

Equation (1) shows that for a total path p the change ΔA of the atomic weight due to spallation is given by

$$\frac{\Delta A}{A_0} = 1 - \exp\left(-\frac{p}{50}\right) \tag{2}$$

where A_0 is the initial atomic weight. For p=20 g.cm⁻², $\Delta A/A_0=0.33$, giving $\Delta A\simeq 9$ for Si²⁸, showing that for p somewhat in excess of 20 g.cm⁻², the elements NeMgSi are converted by spallation to nuclei with atomic numbers below F. The progenitors of F must then largely belong to the SArCa group.

Now the usual abundance ratio SArCa/O is about 1/10, and this value refers for the second component to abundances before spallation. After spallation, O is lost, while the nuclei SArCa become spread over a range of atomic weights perhaps as wide as 20, of which only atomic weight 19 yields F. For the final abundances of F and O in the mixture of both components we therefore have

With the unspalled first component some three times more important than the spalled second component

(O) First component
$$\simeq 3$$
 (O) Second component before spallstion (4)

Combining (3) and (4),

$$\frac{\mathbf{F}}{\mathbf{O}} \approx \frac{1}{60} \cdot \left(\frac{\text{(SArCa)}}{\mathbf{O}}\right)_{\substack{\text{Second component} \\ \text{before spallation}}} \approx \frac{1}{60} \cdot \frac{1}{10}$$
 (5)

which is just consistent with the upper limit set by Comstock et al.². By increasing the importance of the first component still further, the F/O ratio could, of course, be reduced below this upper limit. The discussion given later suggests that equation (5) should be applicable when the energy per nucleon is about 150 MeV, but that F/O should fall below that given by equation (5) at lower energies.

Applying equation (2) for p=20 g.cm⁻², $A_0=10$, gives $\Delta A=5$, while for $A_0=12$, $\Delta A=4$. While these values of ΔA are to be interpreted as averages—there will clearly be an appreciable scatter in ΔA from one nucleus of given A_0 to another—it seems likely that most spallation LiBe is derived from C and that most B is derived from O. Because the C and O abundances are likely to be compar-

able before spallation we obtain

$$\frac{\mathrm{B}}{\mathrm{LiBe}} \simeq 1$$
 (6)

Indeed, if we take LiBe to be distributed according to the number of their stable isotopes* Li³, Li³; Be³ the approximate abundance ratios become Li:Be:B \simeq 2:1:3. Comstock et al.² give 3:2:4. It is interesting that the present model does not lead to as great an excess of B as would occur if the special reaction $C^{12}(p, pn)C^{11}$ were the dominant spallation process.

Next we consider the conditions under which this two-component model might be set up. We regard the spallation as having taken place within the source, not in the Galaxy, thereby avoiding the galactic diffusion model in the quotation mentioned here from Webber's article. In all known sources of cosmic rays, whether supernovae, quasi-stellar objects or radiogalaxies, there exist both the cosmic rays themselves and ambient gas which is detected spectroscopically. For quasistellar objects (QSOs) in particular, there are spectroscopic arguments4 for supposing that emerging light has a path of I g.cm⁻². Hence if QSOs are a major source of cosmic rays, those of high energy $> \sim 1$ GeV per nucleon should have paths of a few g.cm⁻² for the spiralling of the cosmic rays about magnetic field lines must increase the paths to a few times the path length for light. We take this to be the situation for the higher energy cosmic rays mentioned at the beginning of this article. Moreover, in QSOs there is evidence for the existence of discrete clouds of ambient gas. It is from the mixture of such clouds with higher energy cosmic rays that a two-component model for the low energy cosmic rays can be obtained.

In such a mixture, some higher energy cosmic rays will enter and be stopped in the discrete clouds of ambient gas. Consider a cloud exposed to an outwardly directed beam of cosmic rays with energies $> \sim 1$ GeV per nucleon. If the intensity of the beam is small, the cosmic rays will be quenched by the cloud without affecting its motion significantly, but if the intensity is great enough the cloud will experience a strong outward acceleration which may be sufficient to expel it from the system. The velocity of emergence in this case depends on the beam intensity. There could be low velocities of no interest in the cosmic ray problem; there could be velocities so near the velocity of light c that the cloud effectively joins the distribution of higher energy cosmic rays; and there could be the velocities ~ 0.5 c characteristic of low energy cosmic rays.

If we now turn the argument around by requiring the emergent cloud velocity to be ~ 0.5 c, we can estimate the ratio of the cloud mass M to the mass m of the beam. Initially, the outward momentum belongs to the beam and is $mc(1-\beta^2)^{-1/2}$, where $(1-\beta^2)^{-1/2}$ is the average time dilatation factor for the higher energy cosmic rays, say 4, corresponding to an average kinetic energy three times the rest mass. After impact, the outward momentum is required to be 0.5 (M+m)c. Assuming no appreciable deceleration of the cloud on its outward journey, we have

$$0.5(M+m)c = mc/(1-\beta^2)^{1/2}$$

$$M/m = 7 \text{ for } 1/(1-\beta^2)^{1/2} = 4$$
(7)

The heavy nuclei present in the beam experience spallation. Assuming that the chemical composition of the cosmic rays and of the cloud is the same, an equal spallation occurs by reciprocity for the material of the cloud. (Incoming nuclei undergo spallation in collisions with protons of the cloud, while some of the nuclei of the

cloud undergo spallation by incoming protons.) The resulting component therefore has mass 2m and the component unaffected by spallation has mass M-m. For the ratio obtained in equation (7), the unaffected component is three times more important than the component affected by spallation.

It follows from this argument that the relative importance of the two components is not an arbitrary parameter in the model. The relative importance is a function of the energy of emergence of the low energy cosmic rays. Write E as the kinetic energy per nucleon. The corresponding velocity is given by

$$1 + E = \left(1 - \frac{v^2}{c^2}\right)^{-1/2} \tag{8}$$

provided E is written in terms of the nucleon rest mass. In place of the first of equations (7), we now have

$$(M+m)v = mc/(\overline{1-\beta^2)^{1/2}}$$
 (9)

The relative importance is just (M-m)/2m. Equations (8) and (9) determine (M-m)/2m in terms of E, provided $(1-\beta^2)^{1/2}$ is specified. It is easy to see that the component unaffected by spallation becomes more important as E is reduced.

It is likely that the material of a cloud will become ionized. It may not be ionized to begin with, but will become so because of the impact of the high energy particles. The rate of energy loss per nucleon for a relativistic nucleus in ionized hydrogen is ~ 12 MeV per g.cm⁻². For the nuclei of importance in the fluorine problem, SArCa, this is ~ 100 MeV/g.cm⁻². Paths of ~ 20 g.cm⁻² therefore occur when the incident energy is ~ 2 GeV per nucleon. For the mean energy of cosmic rays, ~ 3 GeV per nucleon, the path length somewhat exceeds 20 g.cm⁻². It appears then that the path lengths for the component affected by spallation in this model are not arbitrary either.

To summarize:

(1) Low energy cosmic rays (~ 100 MeV per nucleon) arise from the interaction of higher energy cosmic rays ($> \sim 1$ GeV per nucleon) with ambient gas clouds.

(2) The gas clouds are only partially affected by spallation, so that low energy cosmic rays contain a corresponding component.

(3) The importance of the component affected by spallation is a function of the emergent energy per nucleon, the importance increasing as the energy is decreased. The abundance of LiBeB, which come from the spalled component, should therefore decrease as the energy is lowered. So also should the ratio He³/He⁴.

(4) The component affected by spallation of the low energy cosmic rays has experienced path lengths ~ 20 g.cm⁻², whereas higher energy cosmic rays (> ~ 1 GeV per nucleon) have experienced path lengths which probably do not exceed a few g.cm⁻².

(5) The abundance of F in low energy cosmic rays is small, in part because of the importance of the component unaffected by spallation, in part because of the large path lengths of the other component. The abundances of other odd nuclei, particularly Na and Al, should also be low. The situation here is different from the higher energy cosmic rays. The latter, with paths of $\sim 5 \text{ g.cm}^{-2}$, have odd—even abundance ratios of $\sim 1/3$.

(6) The abundances of the heavy metals of the Fe group should increase as the energy is decreased, because these nuclei come from the unspalled component which becomes more important at low energy.

We have formulated the description of the model in terms of QSOs because the spectroscopic data for QSOs are more extensive than they are for most other sources of cosmic rays. If the cosmic rays are indeed generated in QSOs they are of extragalactic origin and must fill space with an energy density of $\sim 10^{-12}$ erg cm⁻³. If the QSOs

^{*} In private discussion, Professor P. H. Fowler has indicated that Be' is likely to contribute to the Be abundance. Since Be', with its low neutron binding energy, has a very low productive cross-section in some experimentally measured spallation events, we consider that Be' should replace Be' in the text, which otherwise surgives.

are not cosmologically distant objects but lie within a distance of ~100 Mpc, the 105 QSOs estimated from observation have a density of one QSO per 10⁷⁵ cm³, about the same as galaxies^{5,6}. The energetic requirement is for $\sim 10^{63}$ erg of cosmic rays per object. For masses $\sim 10^{13}$ M $_{\odot}$, comparable to large galaxies, the requirement is for 10-3 of the rest mass energy to be converted into cosmic rays. This is a reasonable energetic requirement. If, on the other hand, the QSOs are taken to lie at cosmological distances, the observed density of QSOs is only 1 per 1079 cm3 and the energetic requirement would be raised to ~ 1067 erg per object if the only QSOs are the ones that are currently observed. It is, however, possible to argue that the lifetimes of QSOs are much less than the cosmological time scale of 1010 years, in which case the total number of QSOs over 1010 years would be much greater than those currently observed. Indeed, for an average lifetime of $\sim 10^6$ years the total space density of all QSOs is comparable to galaxies and the energetic

Either way, the requirement is the same as before. energetic requirement is very reasonable.

It may be possible to formulate a similar model for galactic supernovae as sources, provided it can be shown that the ambient gas in supernova remnants has the appropriate properties, and also provided the existence of nearby supernovae can be made plausible.

Two of us (G. R. B. and W. A. F.) wish to thank Churchill College, Cambridge, for the generous hospitality

while this work was in preparation.

Analysis of cores collected from a sequence of lavas in Eastern Iceland has made possible an accurate calculation of the average rate of reversal of the Earth's magnetic field.

DURING an extensive palaeomagnetic survey of Eastern Iceland1, cores were collected from twenty-one overlapping profiles (Fig. 1) so that the chronological sequence of lavas within each profile is known by superposition, and the relationship between the profiles is also known from stratigraphical correlations (Fig. 2). The cores are from a predominantly basaltic succession and range from oldest Tertiary in Eastern Iceland to young Quaternary in age.

The profiles, A to V, comprise a total thickness of 11.0 km of volcanic rocks; they are mostly lava flows and flow units, some 1,140 of which were sampled. (Some lava flows are made up of two or more flow units, all of which are the products of the same volcanic eruption; the units are separated by intervals of time ranging from several hours to several years.) Non-exposure accounts for some 4.5 per cent of the total thickness. Making allowance for repetition by overlap of one profile on another, this represents a succession 8.8 km thick, comprising some 900 separate lava flows and flow units.

Tertiary volcanic centres (Fig. 1) were avoided because of their impersistent stratigraphy, the paucity of basalts, the widespread and often drastic chemical alteration of the rocks and uncertainty as to whether the dip of the lavas is original or secondary. The lower lavas of profile G and the thin lavas of profile N are, however, believed to be parts of central volcanoes. A flexure zone in the area north-east of Nordurdalur (map, Fig. 1) was also avoided.

Interbasaltic clastic beds constitute some 10 per cent of the volcanic succession (Fig. 2). They include many thin red beds (regarded as wind-blown volcanic dust

deposits and usually less than 1 m thick), acid tuffs (including ignimbrites), palagonite tuffs and breccias, tuffs which have been relaid as sediments, conglomerates and tillite like beds. Although only one undoubted tillite has been identified in our succession, several of the clastic beds pass into tillite when traced along strike. Glacial conditions therefore prevailed at several times during the period represented by profiles P to V.

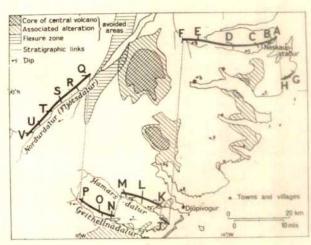

Fig. 1. Map of collecting areas in Eastern Iceland, showing location of

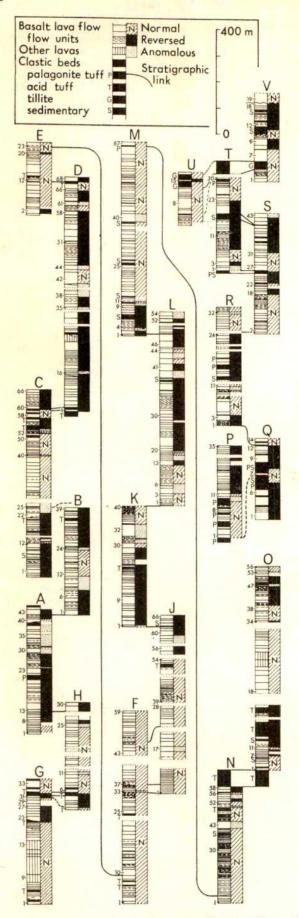

Fig. 2. The lava succession, showing stratigraphic links and magnetic polarity of the lavas.

It should be pointed out that correlation of one profile with another several kilometres away is not often possible because individual lava flows can seldom be traced far. The boundary between two groups of lavas of contrasted petrology or a prominent tuff bed may be used as the basis for a correlation. In neither case is it certain that any of the lava flows of one profile are found in the other, and in the former it is possible that the boundary is slightly diachronous. Of all the correlations, that between P and Q is the least certain, although there is little doubt that the groups of thick clastic beds in the lower parts of these two profiles are equivalent. So far we have collected and measured 2,200 oriented cores (usually two cores from each lava) from 1,070 lava flows or flow units. Except for one small break between profiles O and P, this gives a continuous sequence which starts with the oldest lava accessible in Eastern Iceland (profile G) and ends in the late glacial period.

The mean latitude of the collecting sites is $+64.9^{\circ}$ and, if the Earth's magnetic field is that of a dipole the axis of which is, on the average, coincident with the rotational axis, then the present or Normal field direction in this locality would be 0° E. of N., +76.8° (down), while the Reversed direction would be 180° E. of N., -76.8° (up). After a.c. demagnetization (of all the specimens by at least 150, 250 and 400 peak oersteds) the majority of the lavas give directions which cluster around these two modes, but a significant number have directions which do not lie near the two extremes. In determining the polarity we have defined a flow to be Normally (Reversely) magnetized if both cores give directions within 40° (absolute) of the Normal (Reverse) direction of the dipole field. We have defined as "anomalous" those flows for which the directions of both separately oriented cores agree and fall outside the other two classes. "Discordant" flows for

rejected. They will be studied further to try to resolve the difference. With this classification we find 551 Normal flows, 406 Reversed flows and seventy-three Anomalous flows, forty having had to be rejected.

which the directions of the two cores do not agree were

Nearly all the seventy-three flows with anomalous directions occur between sets of flows showing good Normal and good Reversed directions (Fig. 2). Fifty-five of them show such a high degree of stability that the directions found are considered to define the direction of the ancient field. This suggests that at least the fifty-five "good" anomalous directions are truly Intermediate and indicate how the direction of the Earth's field changed during the transition. If this is so, then the reversal does not simply involve a change in the sense of the dipole. The intermediate directions could be caused either by the continuous change of the dipole axis with possibly also a change in strength or by the reduction in strength of the dipole without change in orientation, allowing the nondipole part of the field to make a proportionally larger contribution and so give the anomalous directions. There are also indications that on some occasions a complete reversal does not take place but that the field finishes up with the same sense as at the start of the excursion. This phenomenon could either represent an only partially delineated event or an as yet undescribed characteristic field variation intermediate between secular variation and

The flows with anomalous directions generally have a much weaker magnetization than the Normal or Reversed flows (Fig. 3). Because it is unlikely that magnetically soft rocks always coincide with a period of transition, the weak average magnetization of the flows with anomalous directions could be caused by a decrease in the strength of the geomagnetic field as it undergoes a reversal. We are trying to measure ancient field intensities for the stable lavas with anomalous directions, so that by comparing the results with those normal and reversed intensities already collected³ the hypothesis can be tested. Sigurgeirsson⁴ has found forty-five lavas in Western Iceland

with anomalous directions which also show low intensity of magnetization and a positive correlation between reversals and low magnetic intensities has been reported in sea cores5-7.

Ten samples from six flows in the lower part of our sequence have been dated (Fig. 4). They indicate a maximum age of about 20×10^6 yr, but because Icelandic basalts are poor material for potassium-argon dating^{8,8}, we do not know precisely the total time span covered by our collection. Dates, however, have been obtained for other Icelandic materials, the oldest of which—10.6 × 106 yr for an obsidian by the potassium-argon method10-can be correlated with profile K of our succession. Edwards (personal communication), however, dates the same material at 6.2×10^6 yr by the fission track method. The ages of the Austurhorn granophyre intrusion, which cuts rocks in profile K and of a granite block in bedded agglomerate at about the same level, have been measured by Gale et al. $^{\circ}$ to be 8.8 and 8.9×10^{6} yr, respectively. It can be argued that these four dates all give minimum ages for the lavas, and lavas below our profile K must therefore be older than about 10×10° yr. Allowing for overlap and considering associated flow units to represent a single flow, our succession is made up of at least 726 independent flows, and so using the present low extrusion rate of 1 lava/40,000 yr (ref. 8) would give 28×10^6 yr as an upper limit. This evidence, taken together with the older basalt dating results, suggests that the oldest lavas in Eastern Iceland are about 20×10^6 yr old. Seven hundred and twenty-six lavas in 20×10^6 yr would mean that each lava represents on the average 28,000 yr.

The present analysis indicates at least sixty-one polarity zones, or sixty complete changes of polarity (Figs. 2 and 4), in our succession. (See results in Western

Iceland, refs. 4 and 30.)

The times at which reversals occurred cannot be defined, but the relative time span of each of the sixty-one zones in our sequence can be judged crudely by the number of the flows or total lava thickness in each zone after allowance has been made for the overlap of different profiles. An important structural characteristic of the basaltic pile of Eastern Iceland needs to be explained; there is a general up-dip attenuation of the lava pile, and at the same time there is a regular upward decrease in the dip of the lava flow averaging 1°/170 m increase in altitude. This means that the succession of lavas in the upper part of a profile is attenuated compared with that in the lower part. Measured thicknesses are therefore not proportional to the duration of time they represent. A correction based on the regular upward dip decreases was applied in the preparation of Fig. 4, to attempt to remedy this situation.

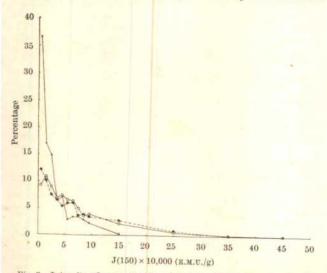

Fig. 3. Intensity of magnetization of samples after demagnetization in 150 oersted peak a.c. field. Each group normalized to 100 samples. ○—○, Normal; • · · · •, reversed; △—△, anomalous.

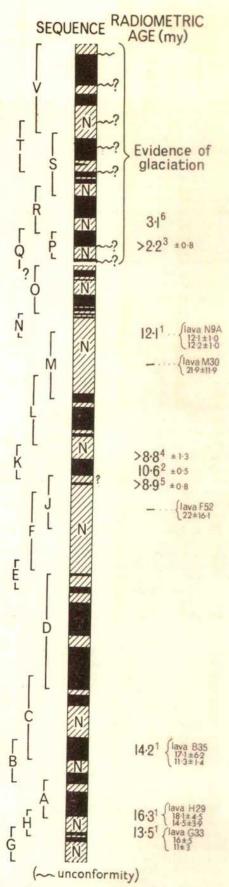

Fig. 4. Generalized succession of polarity zones with thickness modified as discussed in text. K-Ar age determinations: (1) basalt lavas (Grasty); (2) pitchstone (Grasty; Edwards (6:2±0·4)); (3) granophyre intrusion. Hvannadalur (Gale et al., 1966); (4) granophyre intrusion, Austurhorn: oldest of four samples (Gale et al., 1966); (5) granite block in agglomerate, Breidalur volcano (Gale et al., 1966); (6) McDougall and Wensink. 1966, correlation uncertain.

Our sixty inversions in 20×10^6 yr give an average rate of at least 3.0 inversions/10° yr in comparison with the well documented rate of 2.5 inversions/106 yr given by Doell et al.^{10,11}, which becomes 3·1 if the Gilsa⁸ event and a split Mammoth^{12,13} event are real. The sequence of polarity zones built up10,11 from discrete lavas has been amply confirmed by the recent sea core investigations^{5-7,13} which might be expected to provide a continuous record, although the resolution obtainable will depend on the rate of sedimentation. A succession like ours, made up of discrete lavas, cannot claim to be continuous in time, but it is possible, on the other hand, that very brief events will be recorded either if they coincide by chance with a period of extrusion, or if the average rate of extrusion is high enough. Given 40,000 yr/lavas as a low estimate of the average rate, one has an average of twenty-five spot evaluations of the field each 10° yr; 28,000 yr/lava would give thirty-six points. Then many events and epochs should be recorded if there are only an average of, say, 3.0-3.5 inversions/10° yr as shown here. One might even observe a higher rate of inversion than is intrinsically resolvable in some sea cores.

For six polarity zones there is only the evidence from a single lava (N53, O10, O11, O34, S22 and T3). In these cases there are unexposed areas or clastic beds above and/or below the single odd polarity lava flow which indicates that some considerable time may have elapsed between the statement of

between the extrusion of successive lavas.

Two of the polarity zones revealed by our work are particularly noteworthy because of their length (Figs. 2, 4 and 5); E21-23, F1-59, J1-54 contains about seventysix non-overlapping lavas (~ 980 m), while L54, M10-67, N1-52 contains 101 non-overlapping lavas (~ 850 m). Both these are Normal periods. The sixty-one zones shown in Fig. 4 are represented by 726 flows so that there is a mean sequence of twelve flows per polarity zone. The more recent zone in profiles M and N is made of many thin lavas on the flank of an ancient volcano. This suggests a faster than usual rate of extrusion so that the time involved might not be as long as suggested by the number of flows. An incomplete magnetic profile across the same part of Iceland as covered by our survey has been obtained14 using the field mapping technique. At least thirty polarity zones were found, including a long normal zone 1,500 m thick, in the mountains just north of Reydarfjordur. This zone is almost certainly to be identified with the long normal zone in our profiles E, F and J. Several recent studies of magnetic anomalies over ocean ridges have shown them to have remarkable linearity, and symmetry about their axis. The original hypothesis of Vine and Matthews15 that the anomalies are produced by successive strips of normal and reversed material spreading outwards from the axis has now been shown16-18 to be consistent with the polarity epochs reported by Doell et al.10,11 if a suitable rate of spreading is assumed. Pitman and Heirtzler^{17,18} have analysed their results for the Reykjanes ridge, which is a continuation of the central active zone running N.E-S.W. through Iceland. Using a spreading rate of 1 cm/yr^{17,18} (or rather less¹⁹) which compares reasonably well with the rate of 0.6 cm/yr independently suggested by Bodvarsson and Walker²⁰ for Iceland, Pitman and Heirtzler have suggested a polarity sequence back to 107 yr and reaching to 100 km east of the ridge axis. This involves thirty-four reversals or 3.4/10° yr. Their profiles extend beyond 10° yr, and show two relatively long normal zones at BB, CC (Fig. 4, ref. 18), the youngest one beginning just after the thirty-four reversals at 9.0 × 106 yr, or about 90 km from the axis of the ridge. A similar long normal zone is reported between 9×10^6 and 10^7 yr and thirty-eight reversals from the ridge axes in the East Pacific Rise and on the Juan de Fuca Ridge¹⁹. If the top of our succession lies in the Jaramillo normal event (see later discussion), then thirty reversals from that event or thirty-two from the present epoch would take us back into the younger of our two long

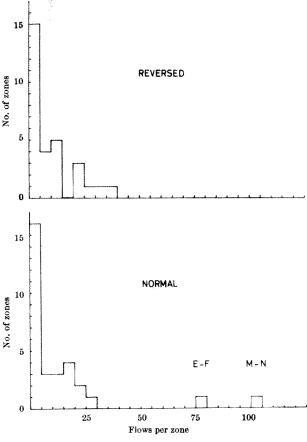

Fig. 5. Histograms showing the distribution of polarity zones according to the number of flows they contain.

normal zones already discussed, which is also about 100 km from the centre of Iceland's active zone. Lava N9A in this youngest normal zone has been dated at 12.1×10^6 yr (Fig. 4), but this lava is known to be quite altered so the date may not be reliable and stratigraphically older lavas in profile K are thought to be only about 10⁷ yr old. The older long normal zone suggested by the Revkjanes ridge profiles CC, but not discussed by Pitman and Heirtzler, starts at about 12.5×106 yr. It is not possible at present to correlate each Normal and Reversed zone in our land survey and in the ocean ridge survey, but it is tempting to correlate our two long normal zones with those found at sea. If this is a world-wide phenomenon one might eventually hope to establish a pair of marker horizons for dating purposes near to 107 yr. It is possible that these zones are associated with the discontinuity in spreading rate of the ocean floor suggested by Ewing and Ewing29

An extrusion rate of 2.8 × 104 yr/lava would suggest 2.0×10^6 and 2.5×10^6 yr for the duration of these two Normal zones M-N and F-J, respectively. McDougall and Wensink's estimate of 4×10^4 yr/lava would give 2.8×10^6 and 3.6×10^6 yr. This is not unreasonable, for evidence21 suggests a much longer reversed epoch during Permo-Carboniferous times, and nearly all the Tertiary lavas collected in Britain have reversed magnetization. Material from the Tertiary collections^{22,23} in Great Britain, and in Kenya²⁴, has been dated. Of twenty-five samples between 20.7×10^6 and 73.7×10^6 yr old, all except two Scottish dykes of $45.0 \pm 1.3 \times 10^6$ yr and $51.0 \pm 6.2 \times 10^6$ yr are reversed. While it is possible that more inversions exist in the lower Tertiary, these results statistically suggest one or more long reversed epochs during the early Tertiary. Vine19 suggests that there may be a decrease in the frequency of reversals at about 25×10^6 yr. The rapid rate of reversal found for the past few million years

may not be a general phenomenon throughout even most of geological time. The rate may vary widely and often; an example is seen between N52 and O11 in our sequence, where there are six inversions in seventeen lavas but none for the next 100 lavas. The inversion rate itself rather than simple polarity might eventually become the characteristic quantity associated with various intervals

of geological time28.

Wensink^{26,27} has reported a palaeomagnetic survey in Jokuldalur some 30 km north-west of our collecting area. Five of his lavas have been dateds and the palaeomagnetic stratigraphy appears to correlate his lava sequence with the Matuyama (R_1) , Gauss (N_2) and Gilbert (R_2) epochs between 1.5×10^6 and 3.5×10^6 yr. The sedimentary bed below the base of profiles P and Q in our sequence is also found near Hofteigur which is below the lowest flow of Wensink's column. Our youngest lava, V19, was collected from the top of the plateau Fljotsdalsheidi, and is normally magnetized but, at the base of Snaefell, about 10 km to the west, a reversally magnetized breccia was found which is apparently younger (personal communication from Einarsson). Although the record of the polarity zones in this area of peneplanation may not be complete, the time gap between the plateau and the breccia is not thought to be very long. This suggests that V19 represents either the Jaramillo or Olduvai normal events. In either case we expect our sequence to include all of

According to Wensink's palaeomagnetic map (Fig. 1, ref. 14) our sequence R to V in Fljotsdalur should lie in the Gauss and older epochs and certainly include the area near Klief, said by Wensink to represent the complete Gauss (N_2) epoch. In fact, Wensink's Kleif profile (Fig. 1, ref. 14) should be our profile T. It shows a single reversed flow in the middle, where we find a reversed zone with twentyfour flows or flow units almost 200 m thick. Wensink describes this as "an inversely magnetized basalt flow intercalated in the N_2 series" and does not include it in his map. The map is based partly on magnetic mapping in the field using undemagnetized samples and it is possible that this method has not revealed all the existing We find it essential to demagnetize all samples before being certain of their polarity, even if the natural remanent magnetism directions of all samples from the same flow are coherent. After thorough a.c. demagnetization, we find sixteen different polarity zones in about ninety-six flows (allowing for overlap) from profiles R-V, which would represent 2.6 × 106 yr at 27,600 yr/flow or 3.8×10^6 yr at 40,000 yr/flow⁸. In the absence of dated materials for this part of our sequence, it would be wrong to try to correlate our series with Wensink's.

This survey was supported by the NERC and the Icelandic Science Foundation. We thank Leo Kristiansson, Jacob Ingvarsson and Gisli Thorstensson for their Potassium-argon dating was carried out at the Department of Geodesy and Geophysics in Cambridge.

Porphyrin Abiogenesis from Pyrrole and Formaldehyde under Simulated Geochemical Conditions

G. W. HODGSON B. L. BAKER Research Council of Alberta, Edmonton

Experiments with gas mixtures intended to simulate primeval atmospheres have yielded a great many types of chemicals of biological interest. It has now been shown that metal porphyrin complexes are commonly produced in these experiments.

THE emergence of photosynthetic tetrapyrrole pigments was fundamental to the establishment of advanced plant life on Earth. In addition, the generation of oxygen in the photosynthetic processes undoubtedly contributed to the accumulation of free oxygen in the atmosphere and thus played a part in the evolution of the oxidizing atmosphere of the Earth. Studies of the primitive atmosphere have shown pathways by which other vitally

important biochemicals may have arisenof systems containing methane, ammonia and water assumed to represent the primordial atmosphere of the Earth¹ involving ultra-violet light or electric discharges has been successful either directly or in stepwise experiments in producing urea², amino-acids³, dipeptides⁴, polypeptides⁵, proteinoids⁶, macromolecules⁷, adenine⁵, guanine⁹, pentose sugars¹⁰, 11, deoxyadenosine¹², ATP¹³ nucleotides and constituents of nucleic acids¹⁴. Allen and Ponnamperuma have also produced fatty acids by this method¹⁵. Thus there is reason to believe that these important constituents of living matter can arise under primitive-atmosphere conditions.

In reporting evidence for porphyrin pigments in extraterrestrial carbonaceous meteorite samples we suggested a biogenic origin for at least part of the carbonaceous matter. The porphyrins in such bodies, however, are not necessarily indicative of fossil life but may alternate

tively represent a pathway by which life arose.

Tetrapyrrole pigments such as porphyrins and dihydroporphyrins (chlorins) are formed biosynthetically from δ-amino levulinic acid and an asymmetrical succinyl derivative¹⁷. Two molecules of the acid are then condensed by a dehydrase enzyme to form porphobilinogen; condensation of porphobilinogen produces the tetrapyrrole

structure uroporphyrinogen III.

For abiogenic production of the porphyrin structure two general approaches are possible. One is the levulinic acid approach using ultra-violet light instead of the enzyme, as demonstrated by Szutka¹⁸. The other approach is to use pyrrole and formaldehyde to produce the porphin ring. In this connexion, pyrrole has been made from acetylene (and ethane) with ammonia at high temperatures (300° C)¹⁹, and preliminary evidence from Ponnamperuma indicates the formation of pyrrole from methane and ammonia in electrical discharge reactions. Rothemund²⁰ in early work on porphyrin synthesis used a mixture of 5 molar pyrrole in methanol, an equal volume of pyridine and a ten-fold volume of 2 per cent formaldehyde in methanol. After heating for 30 h at 90°-95° C in sealed tubes, the reaction yielded free porphin in a 0·1 per cent yield.

The purpose of the present study was to demonstrate the ready formation of metal porphyrin pigments from products of primitive-atmosphere experiments. Reaction conditions simulated geochemical conditions starting with experiments closely related to the Rothemund synthesis²⁰ and leading into an aqueous mineral suspension system in which metal porphyrin complexes were produced under reasonably mild geochemical conditions. The metals selected for the study were those of primary concern in the geochemistry of terrestrial porphyrins^{21,22}

Four experiments were carried out using redistilled pyrrole and paraformaldehyde in evacuated sealed tubes. In these initial experiments with about 2 ml. of pyrrole and 0.5 g of paraformaldehyde, an attempt was made to examine the effect of added cations by including nickel, cupric and vanadyl salts in three of the tubes in amounts of 0.5 g. After heating at 84° C for 3 h the tubes were opened and the contents extracted with benzene to remove any porphyrin compounds that may have formed. For elution chromatography on silica gel, the benzene extract was reduced to dryness under nitrogen and extracted with n-hexane. The hexane solution was put on a silica gel column and eluted with n-hexane to give an n-hexane fraction. In a similar fashion, the benzene residue was next extracted with a mixture of n-hexane and benzene (in equal volumes) and chromatographed giving a corresponding column eluant. In turn, further eluants were obtained: benzene; a mixture of benzene and methanol (in equal volumes); and methanol.

Each of the eluants was evaporated to a few ml. under nitrogen for spectral examination. None of the chromatographic fractions from the reaction tube free of cations showed absorption features recognizable as porphyrin, soret or non-soret peaks. Significant yields of porphyrin pigments, however, were observed in each of the other reaction tubes containing added cations. The pigments were present in all eluant fractions, but predominantly in the benzene eluants. This is in keeping with the general chromatographic behaviour of naturally occurring porphyrins²³. The pigments were evidently free porphyrins rather than metal complexes, as indicated by the typical

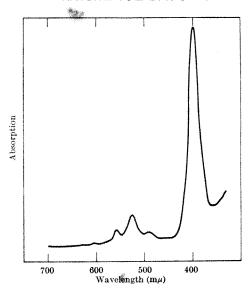

Fig. 1. Spectrum of free porphyrin from reaction of pyrrole with formaldehyde for 3 h at 84° C.

soret and four non-soret peaks of Fig. 1, and by the fact that the pigments fluoresced (red) under 3650 Å ultraviolet light, and complexed readily with copper in acetic acid according to the method of Fischer and Stern²⁴.

The reaction system with added nickel showed the greatest yield of porphyrin pigments, 7.5 μg ; copper gave 1.7 μg , and vanadyl only 0.16 μg . While these yields are exceedingly low (0.002–0.001 per cent) the significant observation is that the formation of the pigments took place and was promoted by the presence of cations, even though the corresponding metal complexes did not form in the course of the reaction.

A second series under reaction conditions of 20 h at 135°C produced principally metal complexes of porphyrins. Although the vanadyl and cation-free tubes produced only enough pigment to make the soret band detectable, the pigment obtained in the copper system had absorption peaks of 3960 Å, 5180 Å and 5520 Å, and that obtained from the nickel system had peaks at 3940 Å, 5100 Å and 5410 Å. Recoveries in this series were: for the copper reaction, 11·8 µg (0·003 per cent); Ni, 4·1 µg (0·0008 per cent); VO, 0·08 µg (<0·00002 per cent); no cation, 0·05 µg (0·00001 per cent).

Water was introduced in later reaction systems to simulate more meaningful geochemical conditions. In reaction mixtures similar to the foregoing, with water added in varying amounts (0·01, 0·1 and 1·0 ml.) to the 2 g mixtures of pyrrole and paraformaldehyde, the presence of water appeared to diminish the yield of metal porphyrin complexes. In this series, the nickel system was the more productive, yielding 1·3, 1·1 and 0·9 µg of metal porphyrin in the systems containing 0·01, 0·1 and 1·0 ml. of water, respectively; the copper yielded little or no porphyrins after 20 h at 135° C.

To explore the effect of other cations in the same reaction conditions, additional experiments with water were carried out. The nickel system produced most pigment although suppressed by the presence of water (yield: 7 μg against 4 μg for the reaction containing 1·0 ml. of water). The copper reaction resulted in the formation of slightly less pigment and vanadyl produced only a trace of porphyrin. Neither ferrous nor ferric cation reactions yielded porphyrin pigments. A mercuric chloride system differed in that it produced a reduced porphyrin, a chlorin, as indicated by non-soret spectral features at 6320 Å and 6650 Å; the soret band was at 3930 Å. Aqueous sealed-tube reactions carried out with copper and nickel at low temperatures, that is at 97° C (for 42 h), produced little pigment materials, again showing the suppressive effect of the water.

To simulate more realistic geochemical conditions pertinent to the abiogenesis of porphyrins, the reaction system was modified so that the pyrrole and paraformaldehyde reactants were present only in small amounts in aqueous reaction systems. Thus a series of aqueous reflux experiments was set up involving nickel, cupric, mercuric, ferrous, ferric and cation-free reactions. The pyrrole, paraformaldehyde and cation contents were about 0.005, 0.003 and 0.005 molar respectively; reaction times were 64 h. Nearly 8 µg of porphyrin complexes was recovered from the reaction with nickel (3890 Å, 5070 Å, 5390 Å). Lack of fluorescence and acid-insolubility clearly showed it to be a metal complex. Small amounts of porphyrin were formed in the reactions with the iron salts, with the yield being slightly greater in the case of the ferric salt.

More effective geochemical simulation calls for the presence of mineral constituents of rocks, primarily to provide solid surfaces which may hinder or promote the formation of porphyrins. As a first approximation, without any direct regard for the rock composition of primitive systems, a supply of crushed rock was prepared from a number of rock samples which had been used in a related study of the occurrence of porphyrins in terrestrial rocks. The rocks were shales, sandstones and carbonates. To prevent the introduction of organic matter (particularly terrestrial porphyrins), the extracted rock samples were ignited at 600° C for a few hours to burn off organic matter.

Relatively low concentrations of the minerals were used—about 0.3 per cent by weight. All six foregoing cations were included as well. About 100 µg of a metal complex (after refluxing for 125 h at 97° C) was obtained (3930 Å, 5180 Å, 5500 Å) (Fig. 2). Spectrally it was similar to a copper complex made from free porphyrin in a related experiment. Mass spectra showed parent peaks at 373 and 371 mass units corresponding to the copper isotope distribution to be expected in copper complexes of porphin (308 mass units). Optical spectroscopy confirmed the copper in the porphyrin complex. Indications were also obtained for parent peaks for the porphyrin at values greater than those of porphin, namely 385 and 387 mass units. The spectral character of the metal complexes was somewhat unusual in that the intensities of the non-soret peaks were reversed, that is $\beta > \alpha$, in comparison with the porphyrins of terrestrial rocks. Such a reversal was observed by Falk²⁵ and related to inherent porphyrin instabilities. Furthermore, it is significant that the cupric complex was produced rather than the nickel favoured in the earlier non-aqueous experiments.

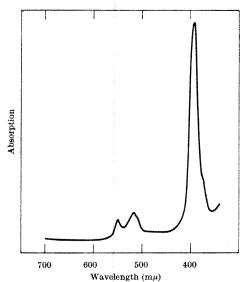

Fig. 2. Spectrum of metal complexed porphyrin produced during aqueous reflux of pyrrole, formaldehyde and added minerals.

A subsequent experiment in which the mineral content was much higher, that is about 10 per cent by weight. and to which about 2.5 per cent of 12 normal ammonium hydroxide was added rather arbitrarily to simulate an ammonia atmosphere, showed similar results. Again an apparent metal complex evolved, even though no cations were added to the system. The spectral features were at 3990 Å, 5260 Å and 5580 Å—somewhat higher than those for the copper complex of the foregoing experiment. In addition there was an appreciable yield of free porphyrin. Thus free porphyrins evidently also form under these conditions, and proceed to metal complexes by taking up cations from the suspended minerals, as noted for free porphyrins in earlier work26 in which standard clay minerals provided complexing cations for biogenic free porphyrins in aqueous systems at room temperature. In all cases, the identity of the complexing cations was unknown, but there was evidence to suggest that they were divalent cations such as copper, zinc or cobalt. The role of magnesium is not clear in this context, although it is known to be very unstable in chlorin complexes as in the chlorophylls and their immediate degradation

In an attempt to determine the identity of the complexing cations in the abiogenic experiment, samples of the free porphyrin formed in the experiment were complexed with vanadyl, iron, silver, copper and magnesium. The absorption spectra of these complexes, as summarized in Table 1, did not, however, correspond with the unknown complexes.

Table 1. ABSORPTION MAXIMA OF METAL COMPLEXED PORPHYRINS Vanadyl Iron Silver Copper Magnesium 3890 Å 3890 Å 5170 Å 3880 Å 5160 Å 4050 Å 3870 Å Soret Non-soret II (β) Non-soret I (a) 5140 Å 5370 Å 5160 Å 5490 Å $5500~{\rm \AA}$ 5640 Å

Some terrestrial porphyrins show evidence in their chromatographic and gel permeation behaviour of biogenic residues, presumably lipids and proteins, associated with the porphyrins. The abiogenic porphyrins in the present study showed no such indications and chromatographic column cluants were strikingly free of background absorption. In the same manner, gel permeation studies on a nickel porphyrin prepared from the free porphyrin in this experiment gave no indication of molecularly associated material with the pigment.

The experiments in this study show that porphyrins can arise under mild geochemical conditions from low concentrations of pyrrole and formaldehyde in aqueous systems. The presence of divalent cations, particularly nickel and cupric, promote the formation of the porphyrins. Cupric and other cations are readily scavenged from minerals in simulated geochemical systems.

The molecular weight of the synthesized perphyrins range from 308 for the simplest perphyrin. Molecular size measurements based on gel permeation show a regular sequence of free and metal perphyrins. Typical spectra for the perphyrins formed under the simulated geochemical condition are somewhat displaced from those for biogenic pigments, the peaks being about 100 Å lower in wavelength for the abiogenic perphyrins.

If porphyrins arise under such mild simulated thermal geochemical conditions, they may, of course, be expected under related conditions involving the input of irradiation energy. This has been shown to be the case for pyrrole and benzaldehyde²⁷, and also for levulinic acid in the generation of pyrrole¹⁸. There is reason therefore to believe that porphyrins might arise directly in primitive atmosphere experiments. In some of his classic electric discharge experiments with methane, ammonia and water vapour, Miller²⁸ found red substances containing components with absorption peaks at 3900 Å and 5400 Å. While the latter were established to be something other than (free) porphyrins which should have shown fluorescence, they were probably metal porphyrin complexes. Their

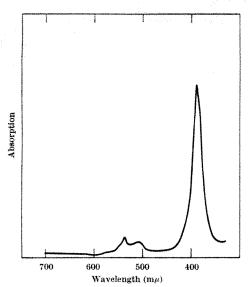

Fig. 3. Spectrum of non-fluorescing nickel complex of an abiogenically synthesized porphyrin.

spectrum was in good agreement with those of simulated geochemical abiogenic synthesis in the present study, such as that shown in Fig. 3.

Thus there is evidence to permit the addition of porphyrins to the already long list of biologically vital compounds which arise under prebiotic primitive-atmosphere conditions. It is important to point out, however, that such an "explosive" porphyrin formation is far removed from the step-wise process of biogenic porphyrin synthesis common to all forms of life at the present time. It is also clear that porphin-like porphyrins generated under abiogenic conditions, such as those in the present study, are considerably short of specific biogenic porphyrins, for example, protoporphyrin IX. The significant point, however, relates to the prebiotic systems, particularly to

the indications that the basic porphyrin structure can emerge directly from simple precursors without dependence on the fairly complex biological steps presently in use, which may have evolved subsequently in developing living organisms.

Numerical Specification of Biological Form

by

B. MELTZER N. H. SEARLE Metamathematics Unit, University of Edinburgh

R. BROWN Botany Department, University of Edinburgh In the study of topics such as morphogenesis, numerical specification of form is particularly important. The authors outline a method, using Walsh functions, which can be used to define a two-dimensional form.

The numerical specification of form is important particularly in the study of morphogenesis. The development of an organ or organism is characterized by a succession of stages each of which may involve distinctive metabolic states and morphological patterns. The change in metabolic state is now being exhaustively examined with considerable success. It is generally recognized that the metabolic state expresses a particular protein pattern. The nature of the pattern and the mechanism involved in determining it can now be examined with some precision.

Change in the morphological pattern, however, still eludes precise definition. Simple inspection shows that change in form is as pronounced as change in metabolic state, but while the one can be examined analytically the other cannot. The difference undoubtedly arises from the fact that, while in one connexion certain attributes of the end product can be expressed quantitatively, in the other they cannot. The total quantity of protein and the relative amounts of different types of proteins can be assessed in numerical terms. The particular characteris-

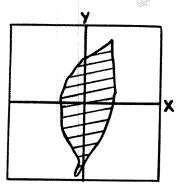

Fig. 1. Object in frame as function.

tics of the morphological pattern are not, on the other hand, amenable to extensive numerical treatment. The change in morphological pattern can only be appreciated in terms of a series of diagrams, which do not provide the basis for an analytical characterization of the change or for an examination of the factors by which it is determined.

Moreover, the present limitation imposes another restraint on the analysis of the morphogenetic process, as at present it is difficult to determine the interaction between the two changing aspects. It cannot be doubted that the metabolic state is linked in some sense to the form by which it is accompanied. Certain metabolic states are likely to promote certain forms of expansion and not others, and localization of metabolic states is likely to lead to differential growth rates which will promote the development of a particular form. The work on the genetical determination of readily distinguishable forms (in, for example, tomato leaves¹) indicates as much. At the same time it is not inconceivable that the change in metabolic state may itself be affected by the change in spatial configuration.

Clearly an elaboration of the techniques available for defining biological form is desirable, and the present paper is intended as a contribution to this problem. The situation is simplified when the pattern is twodimensional and attention has therefore been restricted to foliage leaves; an analysis of change in form with time, however, has not been attempted. The primary purpose has been to elaborate a technique which defines certain quantitative characteristics of the mature form. Several investigations have been concerned with the factors involved in determining leaf shape in particular species, or at different levels along the shoot of a single plant. Melville² described a technique for analysing shape in leaves of species of Ulmus and several workers have examined the change in shape along a shoot by measuring the lengths of particular axes (Njoku³). These techniques are not, however, generally applicable, and the purpose here has been to elaborate a technique which is applicable to all leaves and all stages of development.

In the method described here the two-dimensional pattern is represented by a function taking the values 1 and 0. This function is analysed into a sum of weighted basic pattern functions. The process is very similar to spectral analysis, and in fact the sinusoidal functions of the latter and our basic functions are particular examples of the very useful class of orthonormal functions. The method can be straightforwardly generalized to 3-dimensional forms. An initial application of the method to six leaves of Althea species and two of Coleus species is described.

Consider a two-dimensional form like a leaf, enclosed in a square frame with position specified, say, by Cartesian rectangular co-ordinates, x and y. If we assign the value 1 to points where the object is and 0 elsewhere, we shall have defined a function of position F(x,y), taking only 1 or 0 as possible values, which completely fixes the object in the frame. If as in Fig. 1 we shade those portions of the

frame where F(x,y) has the value 1, we have a vivid representation not only of the object but of this function also. This function can be expressed as a weighted sum of certain "basic" functions which we denote by means of two indices, as follows

$$f_{0,0}(x,y), f_{0,1}(x,y), f_{1,0}(x,y), f_{0,2}(x,y), f_{2,1}(x,y), \dots, f_{i,j}(x,y), \dots \text{ etc.},$$

which take only the values l and -1. Fig. 2 gives a representation of a selection of these basic functions with the regions of value l shaded in. If

$$c_{0,0}, c_{0,1}, c_{1,0}, \ldots c_{i,j} \ldots$$
, etc.,

are the respective weights of the basic functions required for representing the object, then the object function is given by

$$F(x,y) = c_{0,0} f_{0,0}(x,y) + c_{0,1} f_{0,1}(x,y) + \ldots c_{i,j} f_{i,j}(x,y) + \ldots$$

The weights $c_{i,j}$ can be calculated in a rather simple manner and have a simple intuitive interpretation: $c_{0,0}$ equals the area A of the form, while every other weight is a measure of the correlation between the object pattern and the corresponding basic pattern; it is in fact equal to one-half the correlation coefficient, positive values indicating positive and negative values negative correlation.

The weights tend to get smaller as the indices i and j of the basic function increase. This will always be the case and is in fact a necessary condition for the success of the method, for the set of basic functions is actually infinite in number and one requires that the sum converges to a suitable degree of approximation to its correct value in a finite number of terms. The closeness of the approximation can be easily judged, for if one includes only a finite number of the weights, it can be shown that the pattern reconstituted from the corresponding basic patterns bears a correlation to the true pattern given by the ratio of the sums of the squares of the weights to the area A. Thus if all the weights are used, the sum of their squares should be precisely equal to A. So the defined ratio can be used to give the percentage accuracy of the representation.

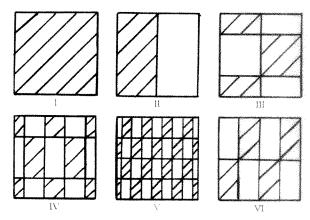

Fig. 2. Selection of basic Walsh patterns; I, $f_{9,0}$; II, $f_{1,0}$; III. $f_{1,0}$; IV. $f_{4,2}$; V, $f_{8,3}$; VI, $f_{1,3}$.

Qualitative features of the forms are reflected in the values of the weights. For example, patterns which are symmetrical about one of the axes must have certain weights zero, and small-scale features in the form reveal themselves in correspondingly large values of some of the higher-order weights. It is clear that it would not be difficult to devise numerical measures of qualitative features of the pattern such as degree of symmetry or

degree of fine-structure, in terms of the squares of the

weights.

The weights calculated do not as they stand specify the form. This can be seen immediately, for if one merely shifted, or rotated, or uniformly contracted or expanded the leaf pattern of Fig. 1, the resulting correlation with the basic function patterns would obviously alter, and so the calculated weights would alter. There are two ways in which one may deal with this problem.

The first method, while involving a considerable computational load, provides an exact specification of form with no arbitrary features. Suppose we fixed on one of the basic functions, say, $f_{i,j}$, and calculated the values of $2c_{i,j}$ for all possible positions, orientations and changes of size of the leaf form within the frame, one would obtain a set of values lying in the range -1 to +1. The algebraically largest of these, that is, the most positive one, would be a measure of the resemblance of the leaf to this basic $f_{i,j}$ pattern, for it gives the maximum correlation possible when one has abstracted the irrelevant factors of location, orientation and size. For a given form, and a given set of basic functions, these maximal weights are uniquely determined, thus constituting an appropriate set of numbers for specifying the form.

In the second method, for a given series of forms—for example, different stages in the development of a leaf—one fixes on some standardization of size, location and orientation in the frame. For a series of the kind mentioned, if one chooses the standardization skilfully, the results can be meaningful and useful. If, however, one wishes to compare one series of forms with another considerably different, it becomes much more difficult to choose suitable standardization for both sets, which would make comparisons meaningful. For the weights calculated are not determined only by the shape of the objects concerned, but also by the particular choice of standard size, position and orientation. However skilful this choice, there is always an element of arbitrariness about it.

There is little doubt that the maximal-weight method is an unequivocal and better method than one using standardization. Because of the latter's comparative simplicity in respect of computation, however, it was used in the initial work reported.

Some experience has now been obtained in analysing leaf patterns. Typically, a coarse analysis giving only the first 16 weights might yield 35 per cent accuracy, while finer ones might give 70 per cent for 64 and 90 per cent for 256 weights. One may therefore have to deal with as many as 256 weights or more.

For purposes of initial and overall survey, it is useful to condense the information contained in the weights. This can be done by grouping weights corresponding to a given structural resolution as follows: with each basic function, $f_{i,j}$, one associates a "resolution", defined as the average distance between successive discontinuities, in both the x and y directions, in the corresponding pattern. If the side of the frame is 1, then

Resolution =
$$\frac{2}{i+j}$$

One adds the sums of the squares of the weights corresponding to a given resolution, and plots these against resolution grouped over equal intervals as in Fig. 3.

These histograms give an intuitively satisfying presentation of the analysis. The large-resolution end of the histogram gives the coarse-structure, "area" type of information about the form; the small-resolution end gives information about fine-structure. The analogy of these histograms to graphs of optical spectra is clear. The abscissa chosen is analogous to wavelength in optics. If the reciprocal of resolution had been used for the abscissa, the parameter would have been analogous to

frequency; this, however, appeared to be rather unsuitable, for it represents the fine-structure components as being orders of magnitude smaller than the coarse-structure ones. This is inappropriate, for it is the fine-structure components which really characterize the shape.

Grouping also has an incidental advantage in that it tends to reduce the effects of the arbitrariness introduced by standardization.

Analysis of Leaves

The preliminary results presented refer to six successive leaves taken from a shoot of Althea species and two leaves taken from the same shoot of a plant of Coleus species. The outlines of the leaves were traced and to simplify computation in the initial stages were symmetrized. With the Coleus leaves the apex was displaced to bring it into the same line as the axis of the leaf. With the Althea leaves the right side was made a mirror image of the left. In the Coleus leaf the serrations at the edge were disregarded and the margin was taken to be a line drawn through the serrations. In all cases the form was taken to be that defined by the lamina and the outline that was analysed was drawn through the point of attachment of the petiole to the lamina.

Table 1. The results from which fig. 3 was plotted Nos. I to VI are leaves from the species *Althea*, and Nos. VII and VIII are from the *Coleus* species.

Resolution				(Weight	$(s)^2 \times 10^5$			
		Coleus						
	1	H	Ш	IV	V	VI	VII	VIII
0-0.067	0	0	0	0	0	0	- 0	0
0.067 - 0.133	876	933	1,216	1,057	1,288	963	702	865
0.133 - 0.2	1,231	1,597	2,102	1,777	2,998	3,497	1,933	1,695
$0 \cdot 2 - 0 \cdot 267$	1,581	1,248	976	1,377	791	510	599	801
0.267 - 0.333	3,200	2,471	3,515	3,116	5,083	5,798	1,515	1,494
0.333-0.4	2,238	2,375	1,917	2,539	2,335	2,004	779	978
0.4-0.467	0	0	0	0	0	0	0	0
0.467 - 0.533	1,600	2,036	1,489	795	669	480	1,052	754
0.533 - 0.6	0	0	0	0	0	0	0	0
0.6-0.667	39	63	232	222	79	227	697	1,328
0.933-1	8,496	7,940	5,885	3,727	3,710	4,436	11,711	10,104
1.933-2	1,893	2,347	3,192	5,464	2,733	1,036	1,487	2,638

The results are given in Table 1 and plotted in Fig. 3 in histogram form. Each histogram is accompanied by a tracing of the leaf from which it is derived. The histograms give only the "low resolution" weights in the range 0-0.667. The large resolution weights are less significant because they are heavily affected by the particular standardization chosen. The six Althea leaves (I-VI, Fig. 3), although they are taken from successive nodes, show a progressive change from a form which is almost entire to one that is sharply palmate. This is reflected in the tendency in the histograms of certain fine structure components to become more prominent. two Coleus leaves (VII and VIII, Fig. 3) although they are also entire are nevertheless lanceolate. Their histograms are similar to each other but in type are remarkably different from those of the first two leaves of the Althea series. It may be noted that the change in the form of the Althea leaves is a reflexion of a corresponding change in the morphogenetic activity of the terminal meristem from which they are derived. The progressive change in the histogram pattern is therefore a numerical characterization of the change in the morphogenetic activity of the meristem.

Mathematical Basis

The basic pattern functions $f_{i,j}$, which are functions of two variables x and y, are synthesized from certain functions of a single variable which were introduced into mathematical analysis by Walsh⁴. Walsh's set of functions constitute what is known as a complete ortho-

normal set; it is this property which they share with the sine and cosine functions of Fourier analysis, which makes them suitable for our purposes.

Each of the basic pattern functions $f_{i,j}(x,y)$ is defined as

$$f_{i,j}(x,y) = f_i(x) f_j(y)$$

where f_i and f_j are the Walsh functions of index i and j

respectively. $f_i(x)$ is defined as follows: Let $i=d_1d_2\ldots d_r$ be the binary representation of the index i, where the d's are 0 or 1, but d_1 is 1. Let s be the value of 1 plus the binary number $d_2d_3 \dots d_r$. Then

$$f_i(x) = \varphi_r^i(x)$$

where $\varphi_{*}(x)$ is defined recursively as follows. Two integral indices n and k are used in the definitions

$$\varphi_{z}^{z}(x)$$
: For $-\frac{1}{2} \leq x < 0$ $\varphi_{1}(2x + \frac{1}{2})$

$$0 \leq x < \frac{1}{2}$$
 $\varphi_{1}(2x - \frac{1}{2})$

For all n > 1 and values of $k, 1, 2, 3 ... 2^{n-1}$:

$$(2x\varphi_{n+1}^{2k-1}(x)): \quad \text{For } -\frac{1}{2} \leqslant x < 0 \qquad \varphi_n^k(2x + \frac{1}{2})$$

$$0 \leqslant x < \frac{1}{2} \qquad (-1)^{k+1}\varphi_n^k(2x - \frac{1}{2})$$

$$\varphi_{n+1}^{2k}(x): \quad \text{For } -\frac{1}{2} \leqslant x < 0 \qquad \varphi_n^k(2x + \frac{1}{2})$$

$$0 \leqslant x < \frac{1}{2} \qquad (-1)^k\varphi_n^k(2x - \frac{1}{2})$$

This definition appears complicated, but the construction of the functions is actually quite simple. The functions are defined for values of x between $-\frac{1}{2}$ and $+\frac{1}{2}$. The The first function φ₀ has the value 1 over this domain. next function φ_1 has the value 1 over the first half of the domain and the value -1 over the second half. The next functions squeeze φ_1 into the first half of the domain and, respectively, φ_1 and $-\varphi_1$ into the second half of the domain. The next four functions repeat the same process on each of the previous two. The following sixteen functions repeat the same process on each of the previous four, and so on, and so on.

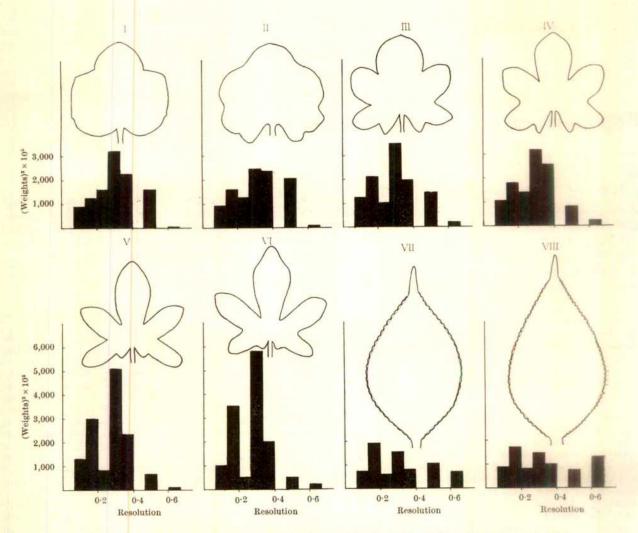

Fig. 3. Outlines and histograms of squared weights for six leaves of species of Althea (I-VI) and for two leaves of species of Coleus (VII and VIII).

The orthonormal properties of the functions are expressed by the following conditions

Orthogonality: $\int f_i(x)f_j(x)dx = 0$ for $i \neq j$ Normality: $\int f_i^2(x)dx = 1$ for all i,

where the integral is over the domain $-\frac{1}{2}$ to $+\frac{1}{2}$ of x.

Our indexing of these Walsh functions is a very convenient one, for it turns out that fi has precisely i discontinuities, that is, jumps between +1 and -1, and that the parity of the function is equal to the parity of the index i.

It follows from the orthonormality of the one-dimensional Walsh functions that the basic pattern functions

$$f_{i,j}(x,y) = f_i(x)f_j(y)$$

are also orthonormal, with the integral concerned now being a double integral over a square of side equal to 1. From the orthonormality it follows that the weights $c_{i,j}$ are given by

$$c_{i,j} = \int \int F(x,y) f_{i,j}(x,y) dx dy$$

To find how this weight is related to the correlation between the object pattern and the basic function pattern, we set

$$g(x,y) = 2F(x,y) - 1$$

thereby ensuring that g(x,y) represents the object pattern by 1's and -1's, unlike f(x,y) which represents it by 1's and 0's. Hence

$$c_{i,j} = \iiint \left[\frac{1}{2} + \frac{1}{2}g(x,y) \right] f_{i,j}(x,y) \, dx \, dy$$

= $\frac{1}{2} \iint g(x,y) f_{i,j}(x,y) \, dx \, dy$

provided i and j are not both 0. It is also easy to see that $c_{0,0}$ equals the area of the form represented by F(x,y). Note that it also follows from the orthonormality that

$$A = \iint [F(x,y)]^2 dx dy = c_{0,0}^2 + c_{0,1}^2 + c_{1,0}^2 + \ldots + c_{i,j}^2 + \ldots$$

where A is the area; hence $c_{i,j}$ tends to 0 as the indices i and j tend to infinity.

It is easily seen, from the parity properties of the Walsh functions, that for a form symmetrical about the y-axis the weights $c_{i,j}$ are zero for all odd i, and for one symmetrical about the x-axis they are zero for all odd j. From the oscillation properties one also sees that small-scale features of a form will be indicated by the $c_{i,j}$ with high indices—the latter obviously will not be much affected by large scale features.

Repopulation of Peyer's Patches in Mice

by

E. P. EVANS

D. A. OGDEN

C. E. FORD

MRC Radiobiological Unit, Harwell, Didcot, Berkshire

H. S. MICKLEM

Department of Zoology, University of Edinburgh

When irradiated mice were injected with bone marrow and lymphoid cells carrying distinct marker chromosome, the pattern of cellular repopulation of the Peyer's patches resembled that of lymph nodes, not that of thymus. This supports the view that the patches are not the analogue of the avian bursa of Fabricius.

WE have already described the patterns of cellular repopulation that are seen in various parts of the lymphomyeloid complex, that is bone marrow, spleen, thymus, lymph nodes and peripheral blood, when myeloid and lymphoid cells (distinguishable by the presence of one or two marker chromosomes) are injected simultaneously into lethally irradiated mice¹⁻³. The thymus was found to differ strikingly from the lymph nodes in showing negligible proliferation of injected lymph node or thymus cells: it was almost entirely repopulated by cells derived from the injected bone marrow. The thymus of mammals differs from the lymph nodes in a number of other ways: it is a lympho-epithelial organ; it plays an important part in both early and adult life in the genesis of immune reactivity. Nevertheless, it does not normally participate directly in immune reactions by, for example, producing immunoblasts, germinal centres, plasmocytes and immunoglobulins. In birds there is, in addition to the thymus,

another important lympho-epithelial organ, the bursa of Fabricius. In birds the thymus seems to control the development of cellular reactivity, while the bursa is responsible for the development of humoral antibody formation⁴. In mammals, too, the thymus is chiefly (although not exclusively) involved in the cellular kind of immunity (allograft rejection and delayed-type hypersensitivity), and Good and his co-workers have therefore been interested in the possibility that there may be an analogue of the avian bursa in mammals⁵⁻⁷. Their recent suggestion⁷ that the Peyer's patches of the intestinal wall might represent such an analogue prompted us to find out whether the Peyer's patches differed from lymph nodes in their pattern of repopulation.

Male CBA mice were exposed to lethal whole-body X-irradiation (1,000 rad) and injected intravenously with $10^5 (CBA \times CBA - T6T6) F_1$ bone marrow cells (containing a single marker chromosome) and $10^7 CBA - T6T6$ lymph

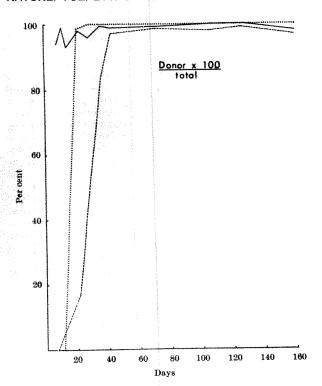

Fig. 1. Percentage of donor-type mitoses in lymphoid tissues of *CBA* mice after lethal irradiation and injection of 10⁵ hone marrow and 10⁷ lymph node or thymus cells. _______, Lymph nodes; ______, Peyer's patches, ______, thymus.

node or thymus cells (containing two marker chromosomes), as described before2. Pairs of recipients (one thymus injected and one lymph node injected) were killed on days 8, 11, 14 (two pairs), 21 (two pairs), 28, 35 42 and 70. Additional individual mice were killed on days 70, 106, 127 and 162. 'Colcemid' (Ciba) was injected intraperitoneally 1.5 h before killing. The mitotic cells in the thymus, pooled subcutaneous and mesenteric lymph nodes and pooled Peyer's patches of each individual were examined cytologically. Methods of preparing lymph node and thymus for examination have been described in Peyer's patches were prepared in detail elsewhere⁸. essentially the same way. It was usually possible to cut them away cleanly from the surrounding intestinal mucosa. Some contamination with intestinal epithelium was nevertheless unavoidable, but control experiments showed that mucosal epithelial cells were not dissociated and spread out by the technique used, so that their mitoses did not contribute to the total scored in the Peyer's patches. Two preparations of thymus and one of Peyer's patches provided less than twenty mitoses suitable for scoring and were omitted from the results. Apart from these, 2,888 mitoses were scored from thymus (mean 131/mouse), 3,520 from lymph nodes (mean 147/ mouse) and 2,793 from Peyer's patches (mean 121/ mouse).

Fig. 1 shows the pattern of repopulation of the three tissues by the donor myeloid and lymphoid cells taken together. In the lymph nodes, donor cells greatly out-numbered host cells throughout the experimental period. In the thymus, host cells were in the majority on days 8 and 11, and in three of four animals on day 14. But by day 21, 98-100 per cent of the cells were of donor origin in all four animals examined, and no further host mitoses were recorded. In the Peyer's patches, host cells remained in the majority for a longer time, forming 63-94 per cent of the total in the four mice examined on day 21, and they were still in a substantial minority in one of two animals on day 35.

Considerable numbers of mitoses derived from the donor lymph node inoculum were found in the lymph nodes and Peyer's patches (Fig. 2). Mitoses derived from the thymus were relatively rare in Peyer's patches; while they were dominant in the lymph nodes the patches were still largely populated by host cells. Only two cells originating from the lymph node or thymus inocula were detected in the thymus, which was repopulated by cells derived from the relatively small bone marrow inoculum.

Once repopulation of the Peyer's patches had begun, the proportion of donor mitoses in them derived from the lymphoid inoculum was at first similar to the proportion present in the lymph nodes of the same individual, except in one mouse, killed at 21 days, which may not have been representative. Tests of homogeneity showed that five of the individual differences were significant. from the mouse just mentioned, all the significant differences were observed in mice killed 42 days or more after treatment.

The proportion of donor cells derived from the lymphoid inoculum decreased rapidly in the first few weeks after their first appearance in both lymph nodes and Peyer's patches. Thereafter the proportion seems to have become stabilized, but at a significantly lower level in the patches than in the lymph nodes. Comparison of the mice given LN cells and killed at and after 70 days revealed no significant heterogeneity either in the lymph nodes $(\chi_*^2 = 2\cdot 13)$; P = 0.35) or in the Peyer's patches ($\chi_{\frac{3}{2}}^2 = 2.68$; P = 0.28). but the difference between the two tissues based on the combined counts for three mice was very highly significant ($\chi_1^2 = 46.49$; P infinitesimal). Similar comparisons for the parallel series of mice given thymus cells and killed at or after 35 days also revealed no significant heterogeneity in the lymph nodes ($\chi_4^2 = 7.45$; P = 0.11) or in the Peyer's patches ($\chi_4^2 = 2.15$; P = 0.71). The difference between the two tissues based on the data from five mice was again highly significant ($\chi_1^2 = 18.85$; P = 0.00002).

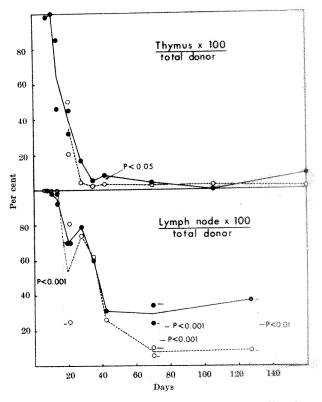

Fig. 2. Proportion of donor cells derived from the lymphoid inoculum in the lymph nodes (♠—♠) and Peyer's patches (○···○) of CEA mice after lethal irradiation and injection of 10⁵ bone marrow and 10⁷ lymph node or thymus cells.

The decrease of the lymphoid component was more rapid in the mice given thymus cells and the final level was significantly lower, although the numbers of lymph node and thymus cells in the original inocula were equal, and their proliferation was measured against the proliferation of an identical bone marrow inoculum. As far as the thymus and lymph nodes are concerned, the results agree with our previous findings2. These tissues were included in the present investigation simply as a yardstick against which to measure the Peyer's patches.

The Peyer's patches differed from the other tissues (and from bone marrow and spleen which were studied previously2) in maintaining a high proportion of host-type mitoses for a longer time after radiation. In the absence of data about the cellularity of the Peyer's patches we can only speculate about an interpretation. Thus we do not know whether the repopulation by donor cells begins later in Peyer's patches than elsewhere, or whether a larger proportion of host cells escape fatal radiation damage in the Peyer's patches than in other lymphoid tissues. A further formal possibility is that relatively undamaged lymphoid cells from various parts of the body tend to circulate after irradiation and become localized preferentially in the Peyer's patches. But whatever the reason for the exceptional persistence of host cells, donor cells finally achieve the same degree of dominance as they enjoy in other tissues.

If the descendants of the lymphoid and bone marrow inocula finally reach a stable equilibrium it is not surprising if the level differs significantly between Peyer's patches and lymph nodes, because the factors influencing repopulation may well differ, if only in degree, between the one type of tissue and the other. At any rate, there is little, if any, discrimination (such as exists in the thymus) against the entry and proliferation of injected lymphoid cells. As far as entry is concerned, this result was predictable from the findings of Gowans and Knight⁹ in rats; they observed that transfused radioactively labelled lymphocytes migrated into the Peyer's patches in the same way as into the lymph nodes.

If we follow the distinction between "central" and "peripheral" lymphoid tissues, the pattern of repopulation of the Peyer's patches aligns them with the peripheral type (lymph nodes) rather than with the one central site (thymus) that has so far been definitely established in mammals. Other features which (at least in guinea-pigs) distinguish the Peyer's patches from the thymus are poor

development at birth, the presence of germinal centres in adults, and failure to develop in germ free conditions¹⁰. In adult guinea-pigs¹¹ and rats (personal communication from G. N. Cooper) the Peyer's patches indeed contain particularly prominent germinal centres. In birds, the bursa of Fabricius resembles the thymus in being well developed at hatching (in contrast to the spleen)12, in not possessing germinal centres¹³, and in developing normally in germ free conditions14. It is not clear exactly how strong an argument against the function of Peyer's patches as a mammalian analogue of the avian bursa these facts constitute. Good \check{et} al. have put a persuasive case for the existence of some kind of analogue⁶ and produced some preliminary evidence supporting this function for the Peyer's patches?. On the other hand, it seems difficult to regard the Peyer's patches as first-order lymphoid tissue on a par with the thymus, and their possession of recirculating lymphocytes, and germinal centres endows them with two important characteristics of "peripheral" or "effector" lymphoid tissue. It remains possible that each patch is in effect two organs—one forming antibody, and the other exercising some undefined influence on antibody synthesis in the lymphoid tissue as a whole.

We thank Mr D. G. Papworth for statistical advice, and Mrs P. A. Smith, Miss B. J. West, Mr M. D. Burtenshaw and Mr P. Embling for technical assistance.

Controlled Fracture of Brittle Solids and Interruption of Electrical Current

by

F. P. BOWDEN J. H. BRUNTON J. E. FIELD A. D. HEYES

Controlled high speed fracture of conducting solids can provide a feasible method of breaking alternating currents at zero current.

Surface Physics, Cavendish Laboratory, Cambridge

A FULL understanding of brittle fracture growth is a problem of both theoretical and experimental complexity. Experimentally, the difficulties arise because fracture frequently starts at a defect of submicroscopic size, and then propagates at velocities reaching a considerable fraction of the stress wave velocities for the material.

With the continued development of high-speed photography and other sophisticated techniques, however, it has been possible over the past few years to study the propagation of fracture in some detail.

Much of the earlier work on fracture was by Schardin', who with Struth² first observed that a maximum crack

velocity of about 1,500 m/sec exists for glass like solids. More recently, in this laboratory, a study has been made of the mechanism of crack propagation in a wide range of materials3-6. One point of significance that emerges is that there are many brittle solids in which cracks can propagate at several thousand metres per second. In order to reach these very high velocities and obtain a clean single crack which runs straight through the solid it is necessary to use carefully controlled conditions. Controlled brittle fracture clearly offers a means for dividing a solid extremely quickly.

We have used the fracture of a brittle conducting solid as a method for interrupting electric current in a short interval of time, typically of the order of a microsecond. With alternating current it has proved possible to use a synchronized fracture process to interrupt the current at (or very close to) zero. These experiments are interesting because they provide a new method for circuit breaking. The normal method for opening a 50 cycle alternating current circuit is by the mechanical separation of metallic This is a comparatively slow process as the breaking time may be milliseconds, and the break may occur at any point on the current cycle. Another method is by the operation of a fuse, and again the interruption is a comparatively slow process.

Table 1. FRACTURE VELOCITY MEASUREMENTS

Material	V _F (m/sec)	$V_F \\ C_1$	VF CR	Comments
Glass (commercial soda-lime)	1,580	0.27	0.51	Isotropic solid; branching of crack at high velocities
Magnesium oxide	5,100	0-56	0.88	Cleavage fracture; branching suppressed
Diamond	7,200	0-4	0.6	Limited number of specimens. VF could be higher
Sapphire	4,500	0.4	0.8	VF for cleavage on {1010}. Fractures frequently con- choidal
Tungsten (rolled, polycrystalline)	2,200	0.43	0.85	Rolling causes some orienta- tion, branching partly sup- pressed

 $V_F = Maximum$ fracture velocity. C_1 = Dilatational stress wave velocity. CR = Rayleigh stress wave velocity.

Table 1 summarizes the results of our fracture velocity measurements. The velocities given are the maximum velocities for the growth of a single fracture (the word "single" is emphasized because situations can arise where a fracture apparently travels at the velocity of one of the stress waves, invariably because the stress wave is initiating many small cracks which subsequently join up to give one fracture). In the case of diamond, relatively few specimens were fractured; the figure for diamond therefore proves that cracks can travel at this speed, but does not rule out the possibility of an even higher

propagation velocity. In the case of the other results are based on the fracture of many Fracture growth was followed by using either and Whitley (Model 189) high-speed camera ultrasonic technique based on a method first Kerkhof and his co-workers (for a review see high-speed camera records were made by the crack edge-on or, alternatively, by growth of the fracture face. This latter me photographing down through the solid, but the detailed development of all the features on face, and shows clearly where measurements growth of a single fracture.

The ratios of crack velocity VF to the stress wave velocity C1 and the Rayleigh s velocity C_R are also given in Table 1, because theoretical estimates of maximum crack usually given in terms of a ratio with one or stress waves. A fuller discussion of these re given in a separate paper yet to be publi general point which emerges is that cracks rea higher velocities in crystalline solids (for magnesium oxide V_F is very close to the Ra velocity) than in isotropic solids like glasses falls midway in this classification; cleave when it occurred, was found most comm {10I0} planes, but many fractures were of nature.) It is interesting to note that at his fractures tend to bifurcate. This bifurcation much more difficult in solids with well-defiplanes. It seems possible that bifurcation limits the velocity of crack propagation in gla but has a smaller effect in solids with well-d of fracture. In these solids velocities app Rayleigh stress wave velocity are attainable is discussed in more detail later in the artic

The surface features which are found on surfaces of crystalline materials have been length in the literature. Gilman7, for exampl screw dislocations can give rise to cleavage then either cancel or add to give the well l pattern". Forty⁸ discusses the formation of fracture surfaces. The present evidence processes occur at relatively low crack veloci Knudsen and Walsh quote a limit of 60 m/s

Two other distinct mechanisms may also roughening or gross bifurcation of a fracture either when the fracture reaches a high velo stress waves interact with the stress field Fig. 1 illustrates the branching whi high crack velocities in glass fractured at

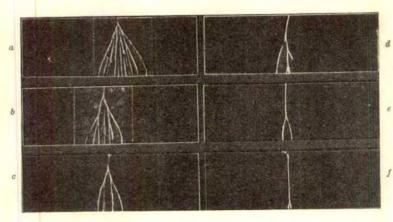

Fig. 1. Glass slides (3 in. \times 1 in. \times 0.05 in.) fractured in a Hounsfield tensometer at different stress levels. The specimens a to f broke at successively lower stress levels showing that the lower the stress level at fracture the longer the path length before crack branching.

of glass slides (3 in. $\times 1$ in. $\times 0.05$ in.) was at the mid-point of one edge of each speciotch sizes were varied as much as possible. s were then fractured in a Hounsfield tensoe and the stress at fracture recorded. As he notch was in the top edge and the speciulled along their length, so that the tennormal to the notch. In la the specimen had notch, which gave only a small stress connd consequently the specimen fractured ess level. As can be seen, there is only a ath before the first bifurcation, and this in ed by further branching. In the remaining specimens were fractured at lower stress they had successively more serious notches) length before branching increased. In stured at lower stress levels than If a single crossed the specimen.

ely, the results show that the length before s inversely proportional to the stress in the re fracture, σ_f , squared, that is

$$\lambda \sigma_f^2 = \text{const.}$$
 (1)

appears to be of broad applicability, for as have been found for other materials and of experimental conditions 11-13. It is not t an equation of the form of equation (1) e, for stress and length are similarly y formulae associated with fracture growth. ergies, equation (1) tells us that the energy before fracture determines the length of

rface roughening and bifurcation.

Bly convincing explanation for branching ent, though two mechanisms have strong first is based on the theoretical work of howed that when a crack reaches a high ress field at the crack tip changes. The ation is usually based on an energy argu-

ment, a point eventually being reached when there is sufficient energy to produce two cracks (see, for example, ref. 13). In our measurements of crack velocities, we find that the crack is still accelerating, albeit slowly, at the branching point. This observation favours the view that branching imposes a maximum velocity in isotropic materials, rather than that the maximum velocity is reached before the bifurcation point. Furthermore, the measured values for the branching velocity have a slight spread. If, however, the two cracks which form the bifurcation are activated by the stress field at the crack tip, then this spread can be explained in terms of a distribution of defects of varying sizes throughout the bulk of the solid. In crystalline solids with well-defined cleavage planes, it is clearly more difficult for cracks to form at an angle to the primary cleavage direction. This could explain the relatively higher fracture velocities in these materials.

The interaction between a stress wave and a fracture may also cause branching. A common situation where this is observed is when fracture is the result of impulsive loading. The dilatational stress wave, set up by the loading, runs ahead of the fracture and reflects at the boundaries of the solid forming a wave of tension which, on its way back through the solid, interacts with the advancing fracture front, causing branching6. In crystalline solids, the available cleavage planes influence the branching process. In diamond the interaction with the stress wave can cause the primary (111) cleavage crack to branch onto two (111) planes at angles to the primary direction. In magnesium oxide, the change in crack direction may be from one (100) plane onto one at right angles to it; this is shown in Fig. 2. The loading in this example was applied by a small explosive detonator at the mid-point of the top edge.

The reflexion of stress waves at the boundaries of the crystal can be prevented by backing the solid with material of the correct acoustic impedance. This is illustrated in Fig. 3, which shows a magnesium oxide

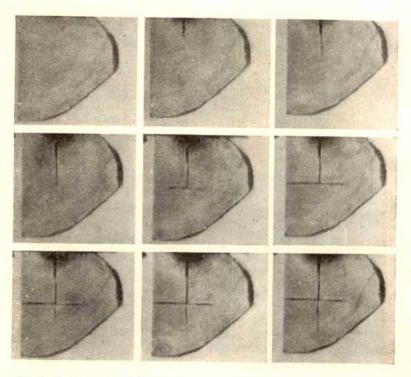

Fig. 2. The fracture of a single crystal of magnesium oxide. The cracks which cut across the specimen from frame 4 onwards are caused when the reflected dilatational wave interacts with the stresses at the tip of the primary crack. The interval between frames is 2-0 microseconds. The length and thickness of the crystal are 3-3 cm and 0-25 cm, respectively.

crystal loaded in a manner similar to that in Fig. 2, but with the crystal mounted on a steel anvil. This time the dilatational wave does not reflect at the lower surface as a wave of tension, and the primary cracks develop smoothly down the specimen.

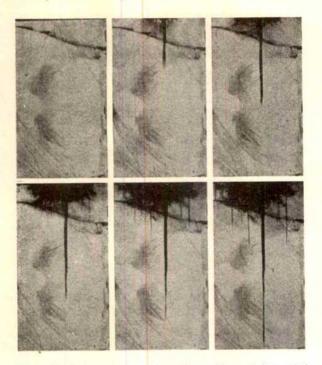

Fig. 3. The fracture of a magnesium oxide crystal mounted on a steel anvil. This time no reflected wave passes back up the specimen and secondary cracking is absent. Frame interval 1-0 µsec.

For a measurement of the speed of fracture growth in a conducting solid, it is possible to devise methods based on the change of one or other of the solid's electrical parameters15,16. In our initial experiments with metals, the change of resistance of a specimen as a crack cut through was measured. This method has the advantage that it gives a continuous measure of crack velocity, but has the disadvantage that the change of resistance is not a linear function of crack length: this restricts the accuracy. Considerably more accuracy can be achieved with the method depicted schematically in Fig. 4a, in which a high frequency a.c. signal is fed onto terminals, one on either side of a notch in the specimen. Under these conditions the "skin effect" operates and the current path is from one terminal, around the notch and to the second terminal (Fig. 4b). When the specimen fractures and a crack extends from the notch, the current path The changing electrical impedance of the specimen is eventually displayed on an oscilloscope as a voltage/time trace from which the crack velocity data can be determined. The frequency of 5 Mc/s was chosen because then the current path followed the shape of the crack without going to the extreme of "cutting corners" (too low a frequency) or of following any surface roughness of the fracture face (too high a frequency). A further advantage of this method is that direct currents or low frequency alternating currents can be passed through the specimen without affecting the crack velocity measurement. The electrical methods are not necessarily restricted only to conducting solids. We have, for example, measured crack velocities in glasses by evaporating conducting films of uniform thickness on to the glass.

The conducting solids so far investigated have been polycrystalline tungsten, molybdenum and silicon iron. The specimens were in strip form, and had notches of chosen size spark eroded into them. Specimen thicknesses

and widths ranged from 0.15 mm to 0.6 mm and 1 cm to 3 cm, respectively. As a general rule, the specimen length was always three times greater than the specimen width; this ensured that the fracture process was over before stress waves reflected from the grips returned to interact with the crack. All the specimens were fractured in a Hounsfield tensometer machine. The work with the brittle metals has shown that cracks can divide the specimen in a few microseconds. As with the glass slides (Fig. 1), bifurcation occurred at high velocities. spread in the crack velocity measurements at which this process took place was, however, greater than with glass. This effect appears to be related to the fact that some metals, when produced in strip form by a rolling process, do have a preferred orientation. X-ray diffraction showed that with tungsten the crystals had effectively a (001) face in the plane of the specimen and a [110] direction parallel to the direction of rolling. When tungsten specimens were cut at various orientations from a large strip, the crack branching occurred more or less readily, depending on this orientation. Measurements of the angles of branching indicated planes of weakness at roughly ±45° to the rolling direction. In specimens cut so that the fracture followed a plane of weakness, the branching was suppressed (compare with crystalline solids discussed earlier) and high velocity single cracks could be produced (see Table 1).

Fig. 5a shows a typical tungsten specimen used in the experiments. It is 1·3 cm wide and 0·15 mm thick. The notch was made by spark erosion and the metal terminals were spot welded into position. Fig. 5b is an example of a tungsten specimen cut so that a plane of weakness lay along the fracture direction. The resulting high velocity fracture was comparatively straight and clean.

Experiments have been performed in which specimens were fractured with steady currents of known size passing through them. As the fracture cuts through the specimen a difference in voltage builds up between the two fracture faces, while the current has to pass through a junction of rapidly decreasing size. Arcing was detected when the voltage exceeded about 18 volts: because the specimens were broken in air under normal atmospheric conditions, this was the value expected. No attempt has been made so far to open up the gap between the fracture faces quickly, or to fracture the specimen in either a high vacuum or in the presence of other gases such as sulphur hexafluoride, or in oil (all procedures which could inhibit arcing).

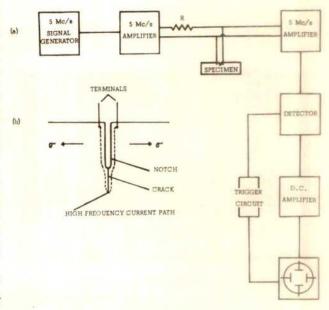

Fig. 4. High frequency fracture velocity method.

The restriction of the current path produces heating in the unfractured part of the solid. Because any heating will make plastic flow at the crack tip more likely with a consequent slowing of the crack, it is important to know the extent of this effect. In a series of experiments with tungsten specimens of width 1.3 cm and thickness of 0.15 mm, we have broken currents of varying size. For currents of less than about 20 amp, no slowing of the crack was detected. For currents of 20 amp and greater, the crack velocity decreased towards the end of its path. Examination of these specimens showed evidence of plastic deformation in the grains near the fracture faces. It is interesting to estimate the current density in the unfractured material when "crack slowing" was detected. For a current of 20 amp, the crack only began to slow down when it was typically 80 per cent across the specimen. This gives a value for the current density of about 5×10^3 amp/cm² in the unfractured solid. It should be emphasized that, even though the crack was slowing down in these experiments, it was still, by normal standards, travelling very fast. It was only when currents greater than about 100 amp were used that crack stopping was occasionally found.

Fig. 6 shows schematically the record on the oscilloscope in an experiment in which a current of 20 amp is interrupted. The top trace is from the apparatus shown in Fig. 4 and gives effectively the length of crack against time from which the velocity is calculated. The lower trace measures the current through the specimen and this is broken in the very short time (less than a microsecond) at the end of the fracture's path through the specimen.

In breaking alternating current it is clearly desirable to do so at as near current zero as possible. An apparatus has been built which fires a pulse at a predetermined point on the alternating current cycle. The pulse can be used to start the fracture process by, for example, firing a small explosive detonator (the reproducibility of our detonators was within 1.5 usec). To prevent the detonator affecting the terminals of the velocity measuring apparatus (see Fig. 4b), it was found convenient to send the pulse from the detonator down a chisel which sat in the notch. It was possible, using this method, to fracture alternating currents sufficiently near the current zero point to produce fast brittle cracks.

From the discussion of fracture it is clear that many intriguing points still need to be settled: enough is now known about fracture, however, to make it a controllable event. The application of a sudden pulse to a notch by, for example, an explosive detonator (a variety of other means is possible) can initiate a fracture in a brittle solid at a required time. The path of the fracture can then be controlled, either by having the specimen already under tension, or by having a plane of weakness in the solid; in

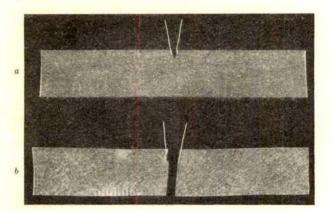

Fig. 5. a, A typical tungsten specimen of width 1.3 cm, 0.15 mm thickness. Terminals are spot welded on either side of the notch for the application of the high frequency current. b, A specimen fractured by a fast fracture. The specimen was prepared so that a plane of weakness lay along the fracture direction.

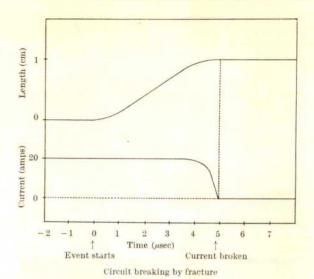

Fig. 6. A schematic record of the fracture of a tungsten specimen carrying a current of 20 amps. The top trace gives length of crack versus time, while the lower trace gives the current through the specimen. The current is interrupted very rapidly.

a crystalline solid the cleavage plane itself would suffice. The velocity of fracture (Table 1) has been measured for a variety of solids, and it is possible to predict fracture velocities with reasonable accuracy in other brittle solids by knowing their elastic properties, and whether fracture is conchoidal or cleavage. The effects of crack bifurcation are reasonably well understood. Stress wave interference can be eliminated, either by careful choice of specimen shape, or by acoustic matching at the boundaries of the solid. The branching which occurs at high velocity obeys equation (1), and therefore if branching is undesirable (in some applications it may not be) and occurs too readily, then the driving stresses can be reduced to give a large path before bifurcation. Experimental evidence shows that a crack quickly accelerates if sufficient energy is available and, for a considerable path length before a branching point, is very near the maximum velocity.

The experiments on metals have shown that high crack velocities can be reached in conducting materials. It is clearly desirable to break alternating currents at zero current and the experiments show that this is feasible. The experiments with direct current indicate the levels for voltage breakdown and the current density when crack slowing begins. These figures give an idea of the tolerance that is required for fracturing near current zero. These observations may be of practical interest for they provide a new method for the very rapid interruption of electrical current.

We thank the Central Electricity Generating Board for a grant to the laboratory in support of A. D. H.

Microwave Background in a Steady-state Universe

Ir has been widely claimed that the background microwave radiation observed by Penzias and Wilson¹ and Roll and Wilkinson² must originate from a radiation dominant, early phase of the Universe. Hoyle and Wickramasinghe³ have, however, discussed the possibility of a more local origin for this radiation. They point out that the energy density arising from the conversion of hydrogen to helium in all galaxies is about 10-13 erg/cm3, close to the energy density of the 3° K blackbody field. If an appreciable fraction of this energy could be thermalized by dust grains the observed "black body" microwave spectrum might be explained. The requirement is that quantum oscillators covering much of the frequency range 0.01 cm⁻¹ to 10 cm-1 are present in the grains. While arguments may be given for the presence of localized oscillation modes within this frequency range, the strongest evidence at the present time would seem to be for the existence of oscillators close to about 10 cm⁻¹ (Sievers⁴, Sievers and Takeno⁵). Such frequencies may be appropriate for the oscillation of weakly bound substitutional impurities in crystals. In a typical case the oscillator strength could be about 0.1 and the line width about 1/10 of the central frequency. We shall consider here the effect of a few strong emission bands at about 1 to 10 cm-1 which may be present in grains. From a total of about 1055 grains in the Galaxy each containing approximately 105 impurity oscillators we could obtain an infra-red emission at about 10 cm-1 equal to approximately 1/3 of the entire luminosity of the Galaxy. This flux of Galactic radiation at v~ 10 cm⁻¹ (1 mm wavelength) could produce the observed excitation of the J=1 rotational levels of cyanogen (CN) (Field and Hitchcock⁶), but it would not account for the microwave observations1,2.

We shall consider the consequences of a similar process operating in other galaxies. It does not seem likely that dust is a phenomenon in any way peculiar to our own galaxy. There is evidence of interstellar polarization in M31 and of interstellar reddening in SMC and LMC as well as of conspicuous striations in many extragalactic objects—all of which point to the presence of dust. If dust is present, it is also reasonable to find effects arising from impurity atoms in the grains.

For a steady-state model of the Universe we shall assume that in every element of proper volume an appreciable fraction of the galaxies contains interstellar dust which can efficiently absorb starlight and re-emit about 30 per cent of the total luminosity of the galaxy through impurity induced resonances at about $10~\rm cm^{-1}$. Quanta emitted from a galaxy at $v\approx 10~\rm cm^{-1}$ will be red-shifted to $\lambda=7.35~\rm cm$ and $3.2~\rm cm$ at red-shifts $z\approx 73~\rm and$ 31, respectively. While galaxies can also absorb radiation at $v\approx 10~\rm cm^{-1}$, the mean free path of an emitted quantum between galaxies is large, about $10^4~\rm mparsec$. This corresponds to a red-shift $z\simeq 3$; thus a quantum with original frequency $v=10~\rm cm^{-1}$ would be red-shifted well outside the width of the absorption band when it encounters another galaxy.

Let N denote the number of galaxies per unit proper volume in the universe. Then the number of galaxies

observed at present with red-shifts between z and z+dz is given by

$$dn = 4\pi \left(\frac{c}{H}\right)^3 N \frac{z^2}{(1+z)^3} dz$$
 (1)

where H is the Hubble constant and c the velocity of light. We shall assume that a fraction α of these galaxies contains interstellar dust and takes part in the thermalization process described. Suppose the amount of radiation emitted per unit time by a typical galaxy in this manner is L, and that this radiation has a normalized spectral function $I(\gamma)$, that is,

$$\int_{0}^{\infty} I(\mathbf{v}) d\mathbf{v} = 1 \tag{2}$$

Because of the expansion of the universe, the observed normalized spectral function from a galaxy of red-shift z is

$$I(z,\mathbf{v}) = (1+z)I(\mathbf{v}.\overline{1+z}) \tag{3}$$

The observed radiation flux per unit time per unit frequency range from a galaxy of red-shift z is therefore given by

$$S(z, \mathbf{v}) = \frac{LH^2}{4\pi c^2 z^2 (1+z)^2} I(z, \mathbf{v})$$

$$= \frac{LH^2}{4\pi c^2 z^2 (1+z)} I(v.1+z) \tag{4}$$

Adding contributions from all galaxies in the universe we get

$$\alpha \int S(z, \mathbf{v}) dn = \alpha \left(\frac{c}{H}\right) LN \int_{0}^{\infty} \frac{I(\mathbf{v} \cdot \overline{1+z}) dz}{(1+z)^{4}} = \mathcal{J}(\mathbf{v})$$
 (5)

 $\mathcal{J}(\mathbf{v})$ dv denotes the total radiation crossing unit area per unit time in the frequency range dv.

We shall first consider the simple case in which the thermalization mechanism in the interstellar dust of each galaxy results in the radiation of a sharp line of frequency v_0 . This corresponds to

$$I(\mathbf{v}) = \delta(\mathbf{v} - \mathbf{v}_0) \tag{6}$$

From equation (5) we get

$$(v) = \begin{cases} \alpha \left(\frac{c}{H}\right) LN \frac{v^3}{v_0^4}, v \leq v_0 \\ 0, v > v_0 \end{cases}$$

$$(7)$$

Thus although each galaxy emits a sharp line, the net contribution from all galaxies results in a continuum spectrum given by equation (7). It is of interest to note that the spectrum continues only on the long wavelength side of the line emitted by a typical galaxy.

Because a general function can be represented as a superposition of suitably weighted delta functions, we can consider the more complicated forms of I(v) by superposing functions of the form in equation (7). The crystallographic properties of interstellar grains are yet to be fully investigated for us to give a precise form for I(v) against ln v. The curve will have a slope of three at the very long wavelengths $(v\rightarrow 0)$. As the range of v overlaps that of I(v), however, the slope will be reduced.

The case where $I(\nu)$ consists of two sharp lines at the original frequencies ν_1 , ν_2 is shown schematically in Fig. 1. We envisage a situation where $\nu_2 \approx 1-10$ cm⁻¹ and $\nu_1 \approx 0.2$ cm⁻¹, the latter frequency lying between the observations of Penzias and Wilson¹ and of Roll and Wilkinson². There is crystallographic evidence for the presence of impurity oscillators around both such frequencies—the former arising from bodily oscillations of a weakly bound

impurity atom, and the latter due to hindered rotations of a diatomic molecule in a crystal^{8,9}. The width of the lines is not relevant because we do not require a coverage by individual lines. It is clear from Fig. 1 that two suitably placed emission lines may give rise to a microwave continuum with a slope of about 2 between $\lambda = 7.35$ cm and $\lambda = 3.2$ cm, in accord with the observations.

It remains to determine the magnitude of the flux arising from our model. From equation (7) the flux arising from a line at $\nu_0 \approx 10$ cm⁻¹ is $\sim 10^{-31}$ erg/cm³ (c/s)⁻¹ at $\lambda \approx 7.35$ cm, assuming $\alpha \approx 1$, $L \approx 10^{43}$ erg/sterad, $N \approx 1$ mparsec⁻³, $H^{-1} \approx 10^{10}$ yr. With $\nu_0 \approx 1$ cm⁻¹ (refs. 8 and 9), and the same values for the other parameters, we get a flux of about 10^{-27} erg cm⁻³ (c/s)⁻¹ at $\lambda \approx 7.35$ cm which is in accord with the observations to within a power of 10

In the preceding calculation the value of total luminosity of the galaxy of about 1043 erg/sterad was assumed. This estimate is based on the observed stellar radiation at visible wavelengths. The energy output of a galaxy in the ultra-violet at $\lambda \le 2000$ Å is uncertain. In young spiral galaxies it could not be ruled out that the total stellar emission in the ultra-violet exceeds the visible output by a factor 10-100. Dust grains present in such galaxies would absorb this radiation with an efficiency factor of about five times greater than for visible light. Thus a galaxy having an optical depth of order unity for visible light will have $\tau \approx 5$ in the ultra-violet. The result is that no ultra-violet radiation can escape from the galaxy. The grains which absorb this energy will reradiate it in the microwave spectral region in the manner described here. The microwave power of galaxies could thus exceed the visible power by a factor of about 100.

Hoyle and Tayler's ¹⁰ estimate of the He/H ratio from the energy output of stars is of interest in this connexion. Taking $L\approx 4\cdot 10^{43}$ erg/sterad as the optical energy output of all the stars in the galaxy they obtain a He/H ratio of about 0·01, resulting from the conversion H \rightarrow He throughout the age of the galaxy. The discrepancy between this estimate and the observed value He/H ratio of about 0·1 would be resolved if the total energy output of the galaxy is about 10 times in excess of that deduced from the optical emission alone.

Our final remarks concern the close equality between the energy density of the microwave background and that of several galactic fields (cosmic rays, galactic magnetic field, etc.) which was pointed out by Hoyle and Wickramasinghe³. It would be a remarkable coincidence if the primordial radiation from a big bang universe possessed the same energy density as these galactic quantities. The present explanation of the microwave background has the

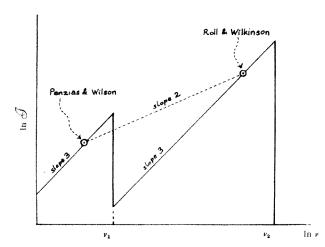

Fig. 1. Schematic representation of a 2-line spectrum with lines at v_1 and v_2 . The dotted line shows how a slope of 2 may be measured between two observational points.

advantage of linking the observed flux with processes currently operating in galaxies.

Diameters of Some Quasars at a Wavelength of 66.9 cm

The measurement of the diameter of radio sources in the range of 10^{-2} sec of arc or less has recently been made possible by a new technique in radio interferometry. Independent stable local oscillators are used to convert the signals at the two stations to frequencies which are recorded on magnetic tapes. In principle, these long baseline interferometers (LBI) can operate at any separation.

Measurements at 49 cm wavelength with a baseline of 220 km $(4.6 \times 10^5 \lambda)$ have been reported by the NRAO—Arecibo group¹, and at the 18 cm hydroxyl line wavelength with a baseline of 845 km $(4.7 \times 10^6 \lambda)$ by the MITNRAO group². Measurement at 66.9 cm wavelength with baselines of 183 km $(2.7 \times 10^5 \lambda)$ and 3,074 km $(4.6 \times 10^6 \lambda)$ have also been reported by the Canadian LBI group³. A further series of observations has been made at 66.9 cm with the 3,074 km baseline during the period July 26–29, 1967, in which fringes of amplitude greater than 4 flux units have been detected from eight sources.

Table 1 shows the fringe visibilities determined from both the $2.7 \times 10^5 \lambda$ baseline (position angle 103°) and the $4.6 \times 10^6 \lambda$ baseline (position angle 95°). The details of the interferometer have been described previously4. Most of the observations were taken near the instrument meridian. The fringe amplitudes were determined from artificial fringes produced by the introduction of coherent c.w. signals at each receiver. The level of these signals was commensurate with the total power output from sources of known flux value, taking into account the bandpass characteristics of the system. The fringe visibilities were then derived from comparison with adopted zero spacing flux values as shown in Table 1. The three highest visibilities at the $4.6 \times 10^6 \lambda$ spacing and the nine highest visibilities at the $2.7 \times 10^5 \lambda$ baseline were nearly equal, and close to unity. A slight adjustment was therefore applied in deriving the values in Table 1 so that the average of each of the groups was normalized to unity. The estimated probable errors of the results are included with each entry. The last column lists source diameters computed on the assumption of a Gaussian model. For sources observed at both separations the data from the longer baseline were used. About forty other sources were observed in the July programme. More elaborate data processing will be necessary, however, to determine their visibilities.

At small elongations interplanetary scintillation could cause a significant reduction in fringe amplitudes. At the time of observation, however, the sources closest to the Sun $(CTA\ 21,\ 3C\ 273B,\ 3C\ 279$ and 1127-14) had

elongations from 60° to 75°. From published data⁵ it is estimated that the effect of scintillation on fringe amplitude is small. The high visibility of 1127-14 supports this conclusion. The sources, 3C 273B, 3C 279, 3C 286, 3C 309·1 and CTA 21 are apparently partially resolved. The detection of fringes at the shorter spacing for the extra-galactic source $\breve{3}C$ 274 supports the suggestion of a small diameter components.

			Table 1		
		S_{448}	Fringe v $2.7 \times 10^{6} \lambda$	isibility 4·6×10°2	Diameter (sec. of arc)

	$\frac{3C}{3C}\frac{273B}{274}\dagger$	19·0 520	$\begin{array}{c} 1 \cdot 1 & \pm 0 \cdot 2 \\ 0 \cdot 02 \pm 0 \cdot 01 \end{array}$	0.5 ± 0.1	0.02
	3C 279 3C 287	12·3 11·8	$\begin{array}{ccc} 0.9 & \pm 0.2 \\ 1.2 & \pm 0.2 \end{array}$	0·3 ± 0·1	0·03 ≤0·1
	3 <i>C</i> 286 3 <i>C</i> 298	22·7 23·0	$\begin{array}{ccc} 0.9 & \pm 0.2 \\ 1.0 & \pm 0.2 \end{array}$	0.2 ± 0.1	0-03 ≤0-1
	3C 309·1 3C 345	$\substack{14.1\\9.0}$	$0.7 \pm 0.2 \\ 0.9 \pm 0.2$	0·3 ± 0·1 1·0 ± 0·2	0.03 ≤0.01
	NRAO 530 3C 446	6·5 11·4	$\begin{array}{cc} 0.9 & \pm 0.2 \\ 1.0 & \pm 0.2 \\ \end{array}$		≤0·1 ≤0·3
	CTA 102 3C 454·3	$7.3 \\ 14.0$	$\begin{array}{ccc} 1.1 & \pm 0.2 & \pm \\ 0.4 & + 0.1 & \pm \end{array}$	1.0 ± 0.2	≤0.01 0.6

* Source not included in observing programme. † It is assumed that 3C 273A is completely resolved at both spacings. † These visibilities were derived for observation laid at the following effective base lines and position angles: 3C 446, 10×10^5 λ and 120° ; CTA 102, 1.5×10^5 λ and 139° ; 3C 454-3, 1.7×10^5 λ and 143° .

The variations of relative local oscillator phase necessary to keep a source on the same interference fringe for sources 3C $27\overline{3}B$ and 3C 345, observed at the longer baseline, were analysed in detail. Over a period of 15 min the variations of apparent local oscillator phase difference with time were fitted with a third order polynomial which approximated the expected variations. The r.m.s. errors were 25° and 70°, respectively. This indicates that even with the relatively low stability of rubidium clocks, valuable information can be derived from phase data for such problems as the synchronization of time and frequency standards at different locations, the determination of relative positions on Earth, the precise measurement of source position and the analysis of source structure. With the more stable hydrogen clocks, the long baseline interferometer will make many new investigations? possible.

PLANETARY SCIENCE

Attitude Determination of the Ariel III Satellite

ARIEL III, the third UK/US satellite, was successfully placed into orbit on May 5, 1967, with apogee and perigee approximately 600 km and 500 km, respectively, and inclination 80°. It had been suggested some time before launch that the spin axis direction required for the interpretation of data from some of the experiments could be monitored by observing fluctuations in the telemetry AGC recordings as the satellite rotated; this method had been adopted for the Ariel II satellite1, but the analysis proved difficult and because the telemetry polar diagrams for Ariel III were found to be nearly circular this technique was regarded as unpromising. An alternative method was therefore proposed similar to that used on Telstar²—namely, observing the glints of solar reflexions from the solar cell panels and from special mirrors placed on the spacecraft. Solar aspect sensors already included in the payload would determine the angle between the spin axis of the satellite and the direction of the Sun, thus defining a conical surface containing the spin axis. To position the spin axis on this cone another frame of reference would be required and the mirror glints would define this. The method was adopted successfully for Ariel III, and spin axis direction to better than $\pm 2^{\circ}$ has been calculated together with coning angle and spin

Six echelon mirrors each with an effective reflecting surface at 30° to the spin axis direction were placed around the body of the spacecraft which was launched with a spin rate of 30 r.p.m. When the spin axis is correctly related to the directions of the Sun and the observer. there are three reflexions every second from the mirrors: similarly, the body solar cells reflect glints at a rate of six a second with the appropriate directions to the spin axis, and the double-sided boom solar cells at a rate of two a second. As an example, with the Sun's direction normal to that of the spin axis there are glints at angles of 25. 60, 90 and 155 degrees to the spin axis direction. The mirrors are rhodium plated and have a 76 per cent reflexion for normally incident light in the visible spectrum while the solar cells have a reflectivity of 20 per cent for normal light. If the mirrors had been optically flat only two or three glints would have been detected during a pass over an observer on the Earth because the Sun's reflexion would illuminate, at any instant, an area of only 5 km in diameter, so it was decided to manufacture them flat to only 1°, thereby giving a 2.5° dispersion of the Sun's image. According to calculations, about ten 7 msec glints of first magnitude would be observed at a ground station in a period of about 4 sec from mirror reflexions while glints from the solar cell panels, which had greater surface irregularities, would each have about 25 msec duration with their glint train lasting for at least 15 sec and the most intense magnitude glint also being first magnitude. As the eye has an integration period longer than the individual glint duration, these glints seem to be about two magnitudes lower to the eye, although photographic and photoelectric devices record the magnitude correctly. An experiment carried out in the laboratory showed that the mirror glints would be easily visible to the human eye through binoculars of magnification 10, although reasonably accurate predictions of the azimuth and elevation of observation would be required. Owing to the number of reflecting surface angles, some glints would be visible on each pass over any station provided the Sun was at least about 10° below the horizon and the satellite was illuminated by the Sun.

A number of organizations agreed to co-operate in the observations and they are listed, together with the type of equipment used, in Table 1.

Two teams of amateur observers controlled by the SAO Moonwatch group and Radio and Space Research Station were also alerted. It is difficult to predict the position along the orbit where glints are expected at a particular station, and so the photoelectric cameras which are capable of tracking the spacecraft from horizon to horizon are the most satisfactory recording system.

Fig. 1 shows the echelon mirrors mounted on the satellite body. They could be adjusted in angular position, and alignment tests were carried out on a flight satellite. The spacecraft was vibrated to the level expected during lift off and the resulting change in alignment was only 1/6°. The final flight model alignment was carried out just before launch when the spacecraft doors had been screwed down for the last time and the full dispersion characteristics of each mirror were determined. The mirrors were found to exhibit different dispersion characteristics, and it is possible on analysis of ground

photoelectric photometry records to indicate which mirror has led to a particular flash.

Since launch there have been many reports of glint observations from satellite tracking cameras and amateur observers all over the world. A sample record from a Baker-Nunn camera in stationary mode is shown in Fig. 2 in which the satellite travels from right to left. The camera shutter was opened just after the satellite entered the field of view. Some remarkable photoelectric records from the Aerospace Research Laboratories, Ohio, have

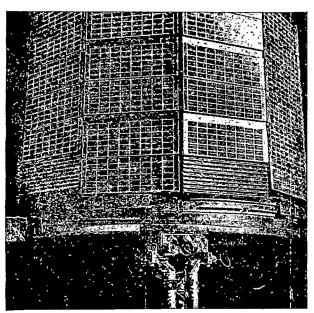

Fig. 1. The Ariel III satellite showing the echelon mirrors fixed to the body of the spacecraft.

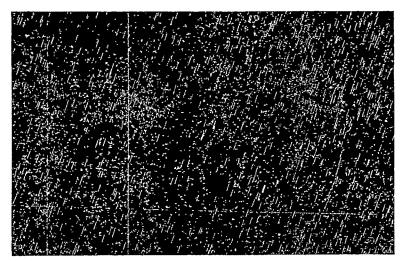

Fig. 2. Glints from body solar cells on Ariel III. Photographed by an SAO Baker-Nunn camera at Island Lagoon, Australia, May 14, 1967.

led to the calculation of the satellite's coning angle, which is the angle between the geometric and dynamic axes, and have shown it to be less than 1°. There is an r.m.s. error in the analysed spin axis direction of about 2° which is no doubt caused by an inability to identify the peak magnitude in the glint train either on photographs or during visual observations by amateurs. The photoelectric data from Ohio, however, have allowed this peak magnitude position to be determined to an accuracy of about 1/6 sec of time. This type of recording is therefore to be recommended in any future use of the optical glint technique. Such a recorder, with azimuth and elevation angle indicated correct to 0·1°, enables the spin axis direction to be measured to better than $\pm 1^{\circ}$ and the coning angle to $\pm 0.1^{\circ}$. Furthermore, a series of measurements of the glints is sufficient to measure these angles without the use of solar aspect sensors, particularly when more than one set of glints can be observed on a single pass. By this means the use of telemetry channels for transmitting solar aspect data is avoided.

The results of spin axis direction during the first 45 days are shown in Fig. 3, the day of the year being marked periodically on the curve with launch occurring on day

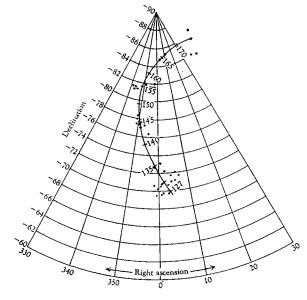

Fig. 3. Ariel III spin axis direction from launch on day 125 to day 170.

Day 125 is May 5, 1967.

Further papers will describe more results and illustrate technical and mathematical features of the technique in more detail.

I thank NASA, SAO, USAF and the Royal Observatory, Edinburgh, for their continuing help in monitoring glints from the satellite and also to the many amateur observers for their valued assistance, the British Aircraft Corporation for their co-operation in carrying out the installation and mechanical tests on the mirrors, and Dr D. E. Smith and M. Colbourne for their help. The Ariel III international co-operative project was managed and supported by the Science Research Council.

Ionospheric Electron Content and the [OI] 6300 A Nightglow

SEVERAL emission features of the night airglow in the tropics are measured regularly at the Haleakala Observatory of the Institute for Astronomy, University of Simultaneously, determinations of the ionospheric electron content are being made by the Department of Electrical Engineering, University of Hawaii, in Honolulu.

The electron content is determined by the Faraday rotation of VHF signals from the synchronous satellite, Syncom III, as received in Honolulu. Determinations are made every 5 min1. A photoelectric photometer with an interference filter2 is pointed at the ionospheric point of the satellite—the point at which the ray path of the satellite signals intersects the ionosphere at a certain altitude on the way to the receiver. We have chosen an altitude of 250 km, at the base of the night time F region and near the height of peak emission rate of the [OI] 6300/6364 Å airglow. The intensity of the 6300 Å emission is measured

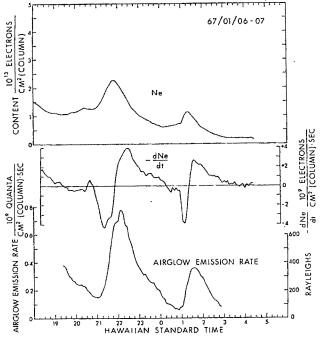

Fig. 1. Observations made in the Hawaiian Islands of the electron content, its time rate of change, and the [OI] 6300/6364 Å nightglow emission rate. The values shown are local zenith values.

every 5 min during the night. Contaminating continuum radiation is eliminated by the so-called two colour method.

Fig. 1 shows the results of these simultaneous observations on the night of January 6/7, 1967. The large night time increases in the intensity of the airglow are peculiar to the tropics3 and these results show that they are preceded by nocturnal increases in electron content. Also shown in Fig. 1 is the negative time rate of change of content, which is expected to be closely related to the airglow emission rate if this large content change occurs in the F region of the ionosphere4. Ionosonde records from Maui, Hawaii, show this to be the case. True height electron density profiles show that the ionization density increases throughout the bottomside F layer, and that the layer falls, during these content increases. The airglow reaches its highest intensity when the ionization reaches its lowest altitude.

From Fig. 1 it may be inferred that about 0.15 quantum is produced for each electron lost in the night time ionosphere. This number includes both the 6300 and 6364 Å emission features. In computing this efficiency, care must be taken to ensure that the ionization source has decayed sufficiently so that the time rate of change of content is primarily a measure of electron loss and not just the difference between production and loss.

The tropical nightglow has several morphological aspects in common with those of the so-called equatorial anomaly of the F region of the ionosphere⁵. This implies that the explanation of the nocturnal increases in electron content is to be found in the peculiar ionization distributions and motions found in the tropics, and not by invoking a night time ionizing agent.

Cool-water Faunas from the Permian of the Canadian Arctic

A LONG established tenet supporting continental displacement has been the presence of Upper Palaeozoic glacial sediments associated with peculiar, presumably cold-loving, faunas and floras in the continents of the southern hemisphere, and the absence of glacial or coldloving biota from the northern hemisphere, even from the Arctic. This suggests that continents now occupying the northern part of the world once lay far to the south, beyond the reach of any northern ice-cap which counterbalanced the southern ice. Thus faunas recently described from the Permian of Greenland¹ and the Canadian Arctic² have virtually nothing in common with the Permian faunas of eastern Australia, where glaciation was particularly intense, to judge from the abundance of glacial varves, and tillites associated with the fossils. Arctic faunas described previously resemble much more closely the faunas of the Zechstein of Germany and Magnesian Limestone of England, where associated salt deposits suggest that waters were warm. Low latitudes for northern Canada are apparently confirmed from palaeomagnetism, Irving³ placing this region between about 10° and 30° north of the Permian equator (Fig. 1). with the North Magnetic Pole situated far away in a position now corresponding with China.

New discoveries of extensive Permian brachiopod faunas by the Geological Survey of Canada cast doubt on this picture, for they include a number of genera allied to long ranging cold-water forms of the Australian Permian. These faunas come partly from

Permian. These faunas come partly from the Arctic Islands, such as Devon Island, and also from the northern Yukon, where Irving³ indicated a palaeolatitude of 20° to 25°. There are three principal cold-water elements, and a fourth more characteristic of slightly warmer waters. Most arresting are distinctive Strophalosiid brachiopods with fine spines and a wedge-shaped dorsal valve as in Wyndhamia Booker (Fig. 2A and D). Wyndhamia is reliably known only from eastern Australia and New Zealand; I have never seen it in collections from Indonesia, south-east Asia, India, Pakistan, Europe or the remainder of North America.

Also abundantly represented are members of the sub-family Licharewiinae. These are transverse spiriferids, usually with pustulose ornament and internal details comparable with the closely allied genus Spiriferella. Licharewia or Permospirifer is common in the Yukon (Fig. 2C), and Pterospirifer and "Spirifer" osborni Harker and Thorsteinsson in the Arctic. This sub-family is prolific in the Permian faunas of eastern Australia, including many so-called Spirifer species, such as forms referred to as vespertilio, phalaena and stutchburi.

The third group are brachythyrid plicate Yukon shells (Fig. 2B) allied to Martiniopsis, and probably congeneric with Tomiopsis Benediktova⁴, or Ambikella Sahni

and Srivastava⁵. The last genus is probably identical with *Ingelarella* Campbell⁶, represented by about fifteen species in both Queensland⁶⁻⁸ and New Zealand⁶⁻¹³. The relationship between *Tomiopsis* and *Ambikella* is not

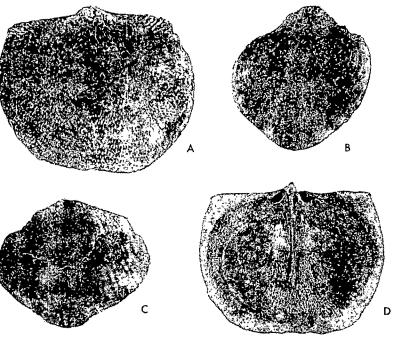

Fig. 2. Permian brachiopods from the Canadian Arctic. A and D are ventral exterior and dorsal interior aspects of? Wyndhamia, from the Assistance Formation (sensu lato). A is from locality 35317, Melville Island; D is from locality 76029, Cape Fortune, Cameron Island, North-west Territories; B is Tomiopsis, dorsal aspect of exterior, from below the Fantasque Formation, locality 36539, Tetsa River area, north of Alask Highway, mile 382, Yukon; C is Licharewia species dorsal aspect of exterior, from same locality. All specimens reproduced natural size, kept at Geological Survey of Canada, Ottaws.

fully established. In Tomiopsis the dorsal median septum seems to arise at the base of the laminated myophore face of the cardinal process¹³ as in the Yukon species. In New Zealand, Indian and Australian Ambikella, the septum commences a little in front.

Another genus represented in the Yukon is Attenuatella Stehli. Although first named from Texas, it is extremely rare in this region (personal communication from G. A. Cooper, Smithsonian Institution), and especially typical of Novaya Zemlya and Taimyr¹⁴ and New Zealand⁹. It also occurs in Peru¹⁵, New Caledonia¹⁶ and to a limited extent in eastern Australia¹⁶.

Whatever the exact generic identities may be, we must conclude that elements of the Canadian brachiopod faunas compare closely with Australian cold-water forms. Canada is not unique among northern countries in this respect. The home of the Licharewiinae and Tomiopsis is the eastern Russian Platform and north-east Siberia, and forms possibly akin to the Canadian Wyndhamia-like shells have been described from Taimyr¹⁴. Furthermore, some of the peculiar Australian bivalve genera seem to be represented in north-east Siberia¹⁷⁻¹⁸, as pointed out by Dickins²⁰. There thus appears to be evidence of a bipolar fauna, with cool or cold-water elements in both Australasia and the Canadian-Siberian Arctic. A latitude as low as 20° N. for the Canadian faunas seems unlikely, palaeomagnetic evidence notwithstanding. In overall appearances the faunas show some similarities to those of northern Queensland, and especially New Zealand. Judging from the distribution of faunas and glacial sediments, Queensland possibly occupied palaeolatitudes of about 70° to 55° S. in the Permian. This accords well with palaeomagnetic data²¹, except that faunas and sediments suggest that only eastern Australia suffered a mid-Permian (Baigendzinian) glaciation, so that the South Pole may have been to the east of the Great Australian Bight, not in the middle as shown by Irving. No palaeomagnetic data are available for New Zealand. The faunas and floras and sediments from this country indicate palaeolatitudes only 10° or so from its present position, perhaps between 55° and 45° S. A slightly lower position would seem acceptable for the Yukon, or even much the same palaeolatitude, if allowance is made for the greater extent of ice in the southern hemisphere. This does not accord well with the palaeolatitude assigned by Irving³, but agrees more closely with palaeolatitudes for north-east Siberia (ref. 3, Fig. 9.9, page 197). While such disagreement may indicate the crudities and risks involved in trying to calibrate palaeolatitudes through faunal studies, it seems feasible to propose that neither Siberia nor northern Canada has moved in phase with the regions where palaeomagnetic work used by Irving was carried out. The tectonic and stratigraphic maps of the Soviet Union suggest buckling of geosynclines on a huge scale, so that if that part of the continent has moved, it has not moved as an undistorted plate, but has crumpled severely. It is certainly difficult to accept palaeomagnetic reconstructions showing the Texas Permian at 15° S. in a palaeolatitude almost comparable with that of the Yukon and Canadian Arctic at 20° N. Dunbar²² also emphasized the considerable difference between his Greenland faunas, supposedly with a palaeolatitude close to 20° N., and those of Texas.

In conclusion, it seems from the nature of faunas that the seas covering northern Canada and north-east Siberia in the Permian occupied temperate rather than subtropical palaeolatitudes, high enough to support a number of cool or cold-water loving genera, at least from time to time, presumably when glacial spasms gripped the southern hemisphere.

I thank the Geological Survey of Canada for lending collections.

Palaeomagnetic Evidence for the Ordovician Geomagnetic Pole Position

I have obtained evidence which supports a pole position in the region of 165° E., 13° N. (antipole 15° W., 13° S.) on the present latitude-longitude grid and relative to the British Isles. This agrees with the palaeoclimatological evidence reported by Spjeldnaes¹, whose studies, based chiefly on the global distribution of shallow water shell deposits, led him to suggest that the Ordovician climatic zones could be deduced from the faunal provinces and that polar ice caps existed during this period. Spjeldnaes1 infers a rotational pole lying in or west of Africa which would correspond to the palaeomagnetic pole at 15° W., These data are not in conflict with Wegener's hypothesis of continental drift, for the positions of the climatic zones on either side of the Atlantic are improved by moving the continental blocks together. There is little corresponding information for the 165° E., 13° N. pole because the data available for China are too few to say whether the palaeolatitude and palaeomagnetic latitude are in agreement. Spjeldnaes concluded from a consideration of Runcorn's2 palaeomagnetic polar wandering curves that a magnetic pole at about 165° E., not far from the Equator, in the region of 0°-25° north of it, would correlate well with the available data.

Oriented hand samples were collected from seven lava flows in the Eyeott group in the Borrowdale volcanic series of Llanvirn-Llandeilo age. Cylinders were cored out of these in the laboratory and an astatic magnetometer was used to measure the remanence of the cores.

			Table 1					
Eycott	Long.	Lat.	α .	Circular standard deviation	Circular standard error	No. of samples	R	Polarity
(1) (2° 56′ W., 54° 40′ N.)	165° E.	14° N.	11·4°	15·1°	5·3°	7	6.794	N.
(2) Llanelwedd (3° 24' W., 52° 9' N.)	162° E.	15° N.	13.9°	21.0°	7-0	9	8-453	s.
(3) Stockenray Bay (4° 54′ W., 55° 11.5′ N.)	168° E.	11° N.	9.50	17.40	5•0°	12	11.495	s.

(Note: Fisherian's statistics used R, σ .)

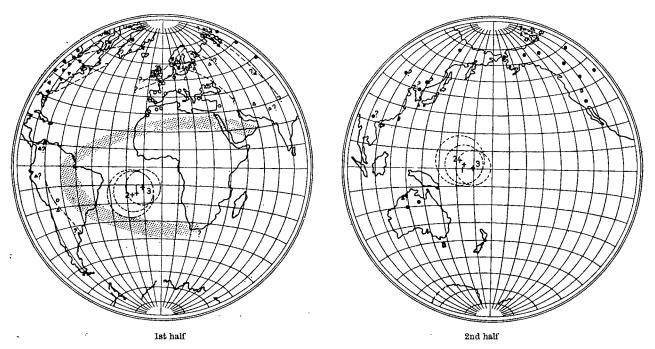

Fig. 1. Comparison of the proposed pole position with Spieldnaes' climatic data. • Tropical faunas; A, warm temperate faunas; A, cold temperate faunas; O, Arctic and Antarctic type faunas. Numbers 1, 2 and 3 refer to the sites in Table 1.

These samples were then subjected to a.c. and thermal demagnetization tests. On the basis of these tests three hand samples were rejected in calculating a mean direction of magnetization. Two of these included the Earth's present field direction within the circular standard deviation of their field directions at the site. The third was strongly magnetized in a direction remote from the remaining samples, but its mean direction began to migrate towards the main group on a.c. cleaning in fields above 560 peak cersteds, moving into the same quadrant after 900 peak cersteds. The specimens initially had a geometric mean intensity 58.7×10^{-4} (S.D. logs 0.37) gauss, susceptibility of 16.0×10^{-3} (S.D. logs 0.42) gauss/cersted, and intensity to susceptibility ratio of 0.37 (S.D. logs 0.37) cersted. A pole position corresponding to the mean direction of magnetization (after cleaning in 85 peak cersteds) was calculated for each flow and a mean pole (Table 1) for the site calculated from these (Fig. 1 (1)).

Evidence supporting this direction was obtained from hand samples of Upper Llanvirn³ age from the Builth volcanic series collected at Llanelwedd in the Builth Wells-Llandrindod inlier. Samples were subjected to a.c. and thermal demagnetization tests on the basis of which three hand samples out of twelve had to be rejected. The mean directions from the other hand samples were combined to yield the mean pole position (Fig. 1 (2) and Table 1 (2)). Most of these samples were very weak with geometric mean intensities in the range 1.2-20.7 × 10-6 gauss and susceptibilities in the range (12.7-52.0) × 10-6 gauss/oersted.

Twelve samples were also collected from four sites in the Arenig lavas in Stockenray Bay south of Girvan. These had a geometric mean intensity of $75 \cdot 0 \times 10^{-6}$ gauss (S.D. logs 0·11), susceptibility of 119×10^{-6} gauss/oersted (S.D. logs 0·18), and intensity/susceptibility ratio of 0·75

Table 2. THE MAGNETIZATION OF SAMPLES FROM STOCKENRAY BAY

	Dec.	Inc.	No. of samples	\boldsymbol{R}	Circular standard deviation	standard error
Horizontal plane Bedding plane	184° 202°	54° 32°	12 12	10·674 8·621	28° 46°	8° 13°
After 85 oersteds Horizontal plane Bedding plane	189° 202°	40° 21°	12 12	11·511 9·216	17° 42°	5° 12°

(S.D. logs 0·12) oersted. It was found that a.c. demagnetization reduced the scatter between samples from the same site and the scatter of the directions between sites, particularly when these directions were referred to the horizontal plane rather than the local bedding direction. This demonstrated that the magnetic age probably corresponds to the age of the folding of these rocks which occurred before the deposition of the Bala sediments which overstep the Arenig rocks of the Girvan⁴ region. This could therefore be an Ordovician direction.

PHYSICS

Growth and Destruction of Ice Filaments in an Electric Field

Modification by electric fields of the growth of ice crystals has been observed under various conditions. Schaefer¹, who was the first to report rapid growth of ice in the form of whisker-like aggregates at high electrical gradients, observed that super-cooled water droplets were projected outwards from the whisker tips. Marshall and Gunn² found that the growth of ice crystals in relatively weak electric fields was initiated as opaque sprouts, which later grew many irregular branches of small cross-section and of no recognizable crystal habit. More recent observations³¹⁴, including studies of the growth of ice crystals in a diffusion cloud chamber, have yielded essentially similar results.

There are three chief factors which indicate the importance of studying the effect of electric fields on ice crystal growth from the vapour phase. First, electric

fields in thunderstorms are most intense, reaching 104 V/cm in the vicinity of the liquid and solid hydrometeors; these charge separations are usually considered to be produced by ice crystal collision and growth mechanisms within the active updraft regions of the cloud. Second, it might be expected not only that the growth of ice crystals would initiate charge separation, but also that this electric field might in turn modify the further development of the ice, thereby altering the charge separation at later stages in the lifetime of the storm. This sort of feed-back process has recently been suggested to account for the rapid, avalanche-like charge generation frequently observed in growing thunderclouds^{6,7}. Finally, as suggested by Bartlett et al.4, the habit variation of ice crystals under the influence of electric fields might lead to an understanding of the basic mechanism of ice crystal growth.

The initial tests were carried out in the absence of an electric field in order to evaluate the crystal growth rates to be expected. The apparatus consisted of a small cold cell, about 5 cm3, in which a water drop could be suspended and viewed from outside. Temperature control was provided by circulating a mixture of petrol-dry ice over two sides and the bottom of the cold cell. water vapour pressure within the cell was maintained at an ice saturation value corresponding to the cell floor temperature; this could be varied between 0° and -40° C and was in general within about 1° C of the working level some 2 cm higher up.

In each trial, a drop of distilled water, 1-2 mm in diameter, was suspended from a fine wire thermocouple and lowered slowly into the cell. This drop served as a source of water vapour, even after its temperature reached that of the surrounding air. It would begin to evaporate slowly, with the water vapour condensing out on the floor of the cell. Immediately after inserting the drop a small ice crystal, attached to a glass fibre, was brought to within a millimetre of the drop, and it commenced to grow rapidly in the vapour field surrounding the drop. This growth was viewed from outside the cell using a low power microscope, and was recorded by time-lapse photography.

The drop usually became nucleated and began to freeze if it was allowed to cool below -15° C; above that temperature it could be artificially nucleated by suspending silver iodide particles in the distilled water. Freezing produced an ice surface at 0° C for a short period of time and resulted in very rapid growth of the ice crystal, almost entirely along the drop-crystal axis. This growth slowed as the drop freezing proceeded and stopped entirely once the completely frozen drop cooled to the ambient Usually the thin filament-like ice air temperature. crystals had bridged the gap before this stage was reached. For a cell temperature of -15° C, the growth rates averaged about 0.1 µ/sec initially when the drop was unfrozen, rose rapidly to 0.8 u/sec as the drop became nucleated and warmed to 0° C, and then decreased, as shown in Fig. 1. As expected, the peak was less pronounced at warmer temperatures, but the difference was not great.

Rough calculations can be made to determine what growth rates to expect in these circumstances. The basic equation is

$$rac{\mathrm{d}m}{\mathrm{d}t} = 4\pi C D (\,
ho_e -\,
ho_e)$$

where ρ_{ϵ} is the environmental vapour density, ρ_{ϵ} is the vapour density at the ice crystal surface, D the diffusivity, and C a shape factor which assumes different values depending on the geometry of the crystal. This may be brought, by the use of the gas law, Clausius-Clapeyron and equivalent heat flow equations, to the form

$$\frac{\mathrm{d}m}{\mathrm{d}t} \approx 4\pi C \frac{\sigma}{f(T)}$$
...

where σ is the supersaturation of the environment relative of ice and f(T) is a function of temperature only. For the initial stage, where the unfrozen drop at -15° C provides the supersaturation, $\sigma/f(T) = 3 \times 10^{-8}$ g/cm sec. value will increase by a factor of ten once the source becomes a frozen drop at 0° C. For a long thin needle, where the length, a, is much greater than the diameter, C may be approximated to by a/3. Thus if the growth is assumed to take place entirely along the needle's length, the growth equation becomes

$$\frac{\mathrm{d}a}{\mathrm{d}t} \approx 4.4 \times 10^{-8} \frac{a}{r^2} \text{ cm/sec}$$
 $\approx 0.44 \text{ }\mu/\text{sec}$

with the diameter of the needles, r, taken as 0.1 mm and the length as about 1 mm.

This is considerably greater than the rate of growth observed with the drop unfrozen at -15° C. conceivably result from thickening of the ice filament as it grows. On the other hand, the observed ratio of 1:8 between growth with the drop unfrozen and that after nucleation is reasonably close to that expected from the equation.

Two parallel brass plates 2 cm apart were used to establish an electric field within the cold cell; the negative electrode was grounded. The drop and the ice crystal suspended from the fibre were introduced as before, midway between the electrodes.

With fields below 200 V/cm no change in the appearance or rate of growth of the ice crystal could be observed. Above this value the growth rate increased rapidly, to 25 μ/sec at 250 V/cm, and reached 150 μ/sec with fields of 1,500 V/cm and the crystals were more numerous, thinner and more fragile; typical examples are shown in Fig. 2.

Another significant feature was the alteration in appearance of these needles according to whether the ambient temperature within the chamber was above or below -12° C. In the former case, opaque sprouts were observed to grow rapidly as thin needles towards the supercooled drop. Under the colder conditions the long thin needles were replaced by even finer, many branched dendritic filaments. These fractured very readily and apparently spontaneously, to be succeeded quickly by a second dendrite, usually growing from the residual stub of its predecessor. In this manner as many as ten dendritic filaments could be observed to grow across the gap between drop and fibre and to shatter one after the other

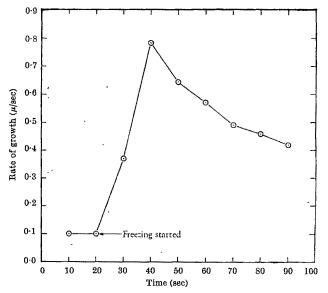

Fig. 1. Typical growth rate curve for the ice crystals in the absence of an electric field. Distance between the drop and crystal tip= 256μ at Distance between the drop and crystal tip=256 μ at T=0. Air temperature = -15° C.

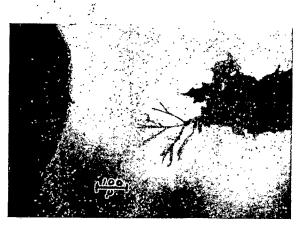

Fig. 2. Branched ice crystal filaments growing in an electric field of 250 V/cm at an ambient temperature of -15° C. The time interval between the two photographs is 10 sec.

during the course of a single drop freezing. This shattering did not occur so readily with the needles grown above -12° C. On the other hand, when such a needle was cooled below -12° C, and allowed to resume growth, it produced the fragile dendritic filaments. Changing the polarity of the electrodes did not in any way alter these observations, the growth being simply towards the vapour source. This does not agree with recent Russian experiments⁸ in which a polarity difference was observed.

A consideration of the electric field distortion around the tip of a thin ice needle or filament can give some indication of the force likely to be responsible for the rapid growth and ultimate shatter. For a long prolate spheroid, the electric field, E, at the tip can be given approximately as

$$Epprox rac{a^2}{b^{ar{2}}}rac{E'}{\lograc{2a}{b}-1}$$

where E' is the externally applied field and a and b are the major and minor semi-axes as before. This equation suggests that the electric field at the growing tip is proportional to $(a/b)^2$, as the term in the denominator varies comparatively slowly. Now, vapour in the vicinity of the tip will be rapidly accreted and will produce further local distortion of the field. In this way a cumulative effect is produced as the crystal grows, until the fragile ice filament shatters.

From the observation of the trajectories and masses of the ejected splinters some idea of the charge carried by them may be obtained. With a field strength of 1,500 V/cm, the largest splinters—about 40µ long—apparently carried average charges of 2×10-4 E.S.U. This value may be compared with that found by Mason and Maybank³ of 10⁻³ E.S.U. after the freezing and shattering of a supercooled water drop, with this total charge being

divided among the twenty to fifty ice crystals ejected by the violent disruption. Hence, the charge carried by each crystal appears to be four to ten times higher in our experiments than in those involving the shatter of a freezing drop.

The possible meteorological significance of the ice needle shattering process may be outlined as follows. As cloud droplets are carried aloft they will be in the presence of an electric field. If any of the theories concerning warm cloud electrification are valid—and a few observations of lightning from clouds entirely warmer than 0° C suggest that they are—these fields could be fairly intense. passing the freezing level, a few ice crystals will begin to appear, either through nucleation onto ice nuclei that were previously dry or, more likely, through the freezing and shatter of a few of the larger droplets. This will produce the combination of factors discussed heresupercooled droplets, ice crystals and an electric field. The ice should grow rapidly as we have observed and, through the action of the electric field, shattering should be common. This will produce increased numbers of ice crystals and, depending on the distribution of the positive and negative charges on the splinters, might further enhance the electric field. This process would tend to increase in frequency as a cascade effect and could produce the rapid glaciation of cloud tops observed by Koenig⁶.

One further point should be noted. The alteration in appearance of the ice needles near -12° C is expected from the changes in crystal habit with temperature described by Mason⁵. The very rapid increase of shattering which was observed when growth took place below this temperature suggests that cascade glaciation might be pronounced only after the cloud top reaches -12° C.

THE SOLID STATE

Morphology of Poly-L-alanine **Spherulites**

Geil¹ and Keith and Padden² prepared small spherulites and hedrites of poly-L-alanine. We have now studied the morphology and structure of such spherulites of larger size and much greater perfection which were formed in essentially 100 per cent yield by casting poly-L-alanine (40 mg) from solution (4 ml.) of trifluoroacetic acid and trifluoroethanol (1:1 v/v). The solvent was allowed to evaporate very slowly (1 ml./12 h) at room temperature from a large watch glass.

The spherulites were subjected to X-ray diffraction, light-scattering, surface replica electron microscopy, infrared spectroscopy and microscopy under polarized light. Fig. 1 is a photomicrograph of two typical spherulites in white light between crossed polarizer and analyser. The

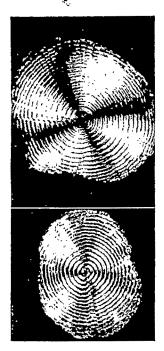

Fig. 1. Typical poly-L-alanine spherulites between crossed polarizer and analyser.

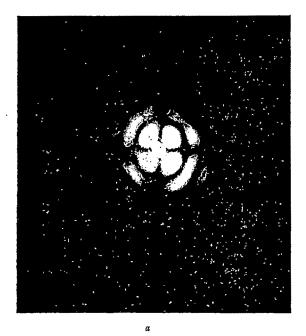

dark cross characteristic of spherulites is clearly visible. The ring and spiral structures are the result of periodic thickness variations, and can be made to disappear by microtoming the spherulite. The average spherulite thickness is about 8μ . The ring-to-ring distance ranges from 6.5 to 9.5 μ and is quite constant for each casting. Spherulite diameters vary from a few tenths of a millimetre to two millimetres. Mechanically, the spherulites are strong but brittle, and cannot be drawn or rolled. The rings apparent in Fig. 1 can, however, be separated quite easily, somewhat like the rings of an onion slice. This suggests that few, if any, polymer chains connect adjacent rings—this is supported by the observation of

cut and tilted spherulites in the polarizing microscope, using a $\lambda/4$ plate—regions of material with very little birefringence were observed to separate the rings. The spherulites are very stable, and have not degraded under ambient conditions during 6 months in this laboratory. A small negative birefringence is observed by Becke line inversion, with $n_r \cong 1.485$, $n_t \cong 1.490$.

The X-ray powder diffractometer pattern shows a very intense line at 7.00 Å, and several poorly defined peaks at 3.73, 4.26, 4.37 and 4.79 Å. These cannot be assigned unequivocally to the α - or β -form of the polypeptide3. A stack of whole spherulites, oriented similarly by pressing into a pellet, gives a normal powder pattern for all orientations relative to the X-ray beam. suggests that there is no preferred chain orientation in the whole spherulite. Only diffuse small-angle scattering is observed for this sample. Diffraction patterns of a group of similarly oriented spherulite segments, however. show a pseudo-fibre pattern. When the radius of the segment is along the equatorial direction of the film, the most intense pair of arcs (7 Å spacing) is also equatorial. If the main chain direction were radial, the arcs would correspond to the fibre repeat of the ordinary β -structure.

Infra-red spectra show the N-H deformation band at 1,525 cm⁻¹ (ref. 4) which is usually associated with the β -form of poly-L-alanine. The carbonyl absorption peak is too wide for assignment to either form.

Small-angle light-scattering from a single spherulite results in the patterns of Fig. 2, obtained with a Spectra-Physics 130 laser on Polaroid 57 film. The observed well defined four-lobe pattern is predicted theoretically by Stein et al. for two-dimensional spherulites with unique radial and tangential polarizability; the pattern therefore indicates that these structures have a high degree of perfection. The photographs of Fig. 2 were taken in the H_{ν} mode—that is, vertically polarized incident light and a horizontal analyser between sample and recording film. The additional arcs just beyond the four principal lobes are not predicted for small-angle scattering from a spherulitic structure. The concentric rings just visible at high angles in Fig. 2b have irregular intensity along the azimuth. Theory predicts maxima at azimuthal angles of 45° corresponding to the ring texture, if the latter is

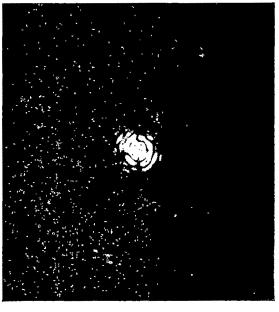

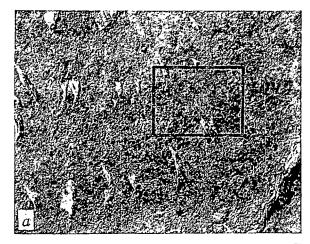

Fig. 2. a, H_v-mode light scattering from a poly-L-alanine spherulite immersed in liquid of refractive index n = 1.488. Distance from sample to plate is 47 cm; exposure time is 1/100 second (×4). b, Same conditions as a. Exposure time is 1/50 second. The weaker high-angle reflexions are now clearly visible (×1).

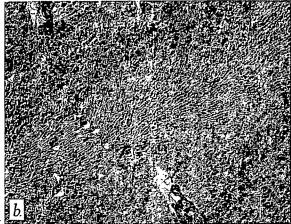

Fig. 3. a, Electron micrograph of surface replica of part of a poly-Lalanine spherulite. (×3,000.) b, Enlargement of the section indicated in a.

due to the periodic anisotropy fluctuation in the radial direction. Because the wide-angle rings in Fig. 2b are equivalent to spacings of $6.5-9.0\mu$, in agreement with the ring-to-ring distance in the micrographs (Fig. 1), it is logical to associate them with the same periodic anisotropy in the radial direction. The same wide angle rings were present in the V_v patterns. The reasons for the large number of lines in the scattering pattern and for some barely visible fine structure in the central lobes of the scattering pattern are not yet clear. Spherulite sizes measured from the radial extent of the lobes agree with those obtained microscopically.

Electron micrographs of carbon replicas show well defined tangential ridges corresponding to the ring structures of Fig. 1. Fig. 3a is a typical photograph; the width of one ring is defined by a series of fissures which arise from strains caused by loss of solvent. An enlarged section of one ring is shown in Fig. 3b.

On the basis of this evidence—primarily the small negative birefringence, separability of rings, X-ray diffraction from spherulite segments and electron micrographs—we suggest that the spherulite in Fig. 1 consists of tangential, twisted lamellar ribbons of irregularly folded poly-L-alanine chains. The polymer chains fold within the plane of the ribbon with their long axes normal to the ribbon axis. The data do not allow an unequivocal assignment of the poly-tr-alanine to the α - or β -configuration. The morphology of the interstitial material between rings also is not yet clear. Both these questions may be answered by electron diffraction experiments now in progress.

Oxidation of Iron-Chromium Binary Alloys

RECENT results1 show that for the oxidation of ironchromium alloys containing 16-38 per cent chromium, in oxygen at atmospheric pressure, the process is controlled by diffusion during the first 2 h of exposure at temperatures between 650° and 950° C. The parabolic rate constants, derived from the linear relationship between the square of the gain in weight and time, showed the expected increase with increase in temperature, but there seemed to be an unexpected minimum in the rate, as a function of alloy composition, at about 20 per cent chromium, as shown in Fig. I. The same trend is shown by weight gain values after longer periods of oxidation and also by the results of another, less detailed study of iron-chromium oxidation2. There is also some evidence that the minimum shifts slightly from 20 per cent chromium to higher chromium contents at lower oxidation temperatures.

The tentative explanation put forward to explain the small increases in oxidation rates at the higher chromium contents was an extension of a suggestion by Mortimer and Menzies3. The scales on the alloys rich in chromium are thought to consist of nearly pure chromic oxide, while the films formed on the iron-chromium alloys, showing the slowest oxidation rates, are chromic oxide doped with small quantities of ferric oxide in solid solution. The pure chromic oxide has p-type conduction4,5 and predominantly cationic vacancies and diffusion6,7. Increasing substitution in the chromic oxide of iron, capable of existing to some extent as Fe2+, would progressively reduce the cation vacancy concentration and sup-

press the p-type conductivity. At higher iron contents there might be an approach to the ferric oxide structure with anion vacancies, increasing anion diffusion, and n-type conduction, No direct evidence was available for this change in defect structure, however, nor for the composition at which it might occur. Such a process might have important effects on the stresses, formed in the oxide films and consequently on the long-term oxidation resistance of these alloys. We present here further evidence for this mechanism and indicate the chromic–ferric oxide composition at which the p to n transition occurs.

Samples of ferric-chromic oxide were prepared by cold pressing and sintering intimate mixtures of the 'Analar' Homogeneity was confirmed by X-ray grade oxides. diffraction and electron probe analysis and the density was found to be about 90 per cent of the theoretical value in every case. The d.c. electrical conductivities were measured by a two-point contact method over a range of temperatures similar to those used in the oxidation studies. For each composition, identical resistances were recorded at both increasing and decreasing temperature intervals. The results of a.c. measurements were within 5 per cent of the d.c. values. The absence of surface leakage and contact resistance effects was confirmed by three- and four-point d.c. experiments. Polarization effects were negligible, as would be expected from the very low ionic transport numbers¹³.

The experimental results, giving resistivity as a function of ferric oxide content, are plotted in Fig. 2 and show that maxima are obtained at all temperatures at about 3 mole per cent of ferric oxide. Fair agreement is obtained with the results of other workers on samples of pure chromic oxide^{4,14} and ferric oxide^{11,15}. The positions of the maxima shift slightly to higher ferric oxide contents at the higher temperatures. This indication that higher doping levels of ferric oxide are required to obtain the maximum resistance at higher temperatures is in qualitative agreement with the observation that higher iron levels conferred maximum oxidation resistance on the alloys at the higher temperatures. After the resistivity-composition curves of Fig. 2 had been obtained the signs of the thermoelectric powers of the samples were determined by establishing a temperature gradient along them. It was found that the semi-conductivity changed from p-type on the low ferric oxide side of the maximum to n-type on the high ferric oxide side exactly as suggested in the original paper¹.

The only remaining evidence required to confirm the mechanism put forward to account for the minimum

oxidation rate is a measurement of the iron concentrations in the oxide scales formed on the alloys. This is, of course, very difficult for the thin scales formed on the slowly oxidizing alloys (16 per cent chromium and above), and in any case there is some variation of composition with time of oxidation. Fig. 3 shows a plot of the iron contents of the scale forming in the first few hours of oxidation at 950° C as a function of the chromium content of the alloy. There is a remarkable correlation, the alloy with the maximum oxidation resistance forming the oxide with maximum high temperature electrical resistivity.

It is interesting to note that the electrical conductivities14 in the analogous chromic-aluminium oxide solid solution system¹⁶ show a trend similar to the ferricchromic oxide results. Despite some uncertainty^{17,18}, the anion vacancy is thought to be the predominant defect in aluminium oxide at temperatures below 1,200° C¹⁹⁻²¹, but because the defect concentration is less than that in ferric oxide it is understandable that 10 mole per cent of aluminium oxide is required to achieve the p-n transition compared with only 3 mole per cent in the case of ferric oxide (Fig. 4). The difficulty with measurements of electrical resistance, however, is that the ionic and electronic components are not easily separated and direct measurements of cation and anion diffusion rates as functions of oxide composition are desirable. In spite of this, providing that electron/hole mobilities do not vary greatly with composition, the density of the charge carriers, and hence the conductivity, is directly proportional to the ionic defect concentration. Consequently the change in the sign of the charge carriers and the minima in conductivity and oxidation rates do suggest that at this critical level of 3-4 mole per cent of ferric oxide the vacancy concentration is at a minimum and the oxide

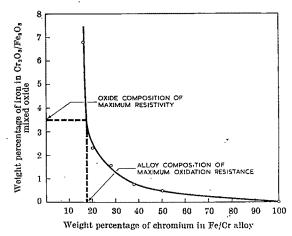

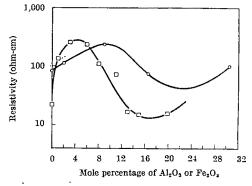

Fig. 3. Composition of oxide forming in 0-18 h oxidation at 950°C.

. Fig. 4.. Effect of Al₂O₂ (O, ref. 14) and Fe₂O₃ ([], this work) additions on resistivity at 1,000° C of Cr₂O₃.

composition approaches perfect stoichiometry. The relatively small associated decrease in oxidation rate of alloys forming oxide of this composition may indicate that vacancies of both types are present throughout the whole composition range and that a small excess of one kind is replaced by a small excess of the other.

A surprising feature of these results is that the transition from p to n occurs at such low ferric oxide contents. Attempts to calculate this critical composition, from experimentally measured defect concentrations 5,11 or stoichiometries, gave values from 0.6 to 20 mole per cent depending on the values selected and their interpretation.

The measurements of high temperature conductivity and thermoelectric e.m.f.s reported here provide a satisfactory explanation of the minima observed in the oxidation rate versus alloy chromium content curves. This is the first direct experimental evidence that oxide scales with anion defects give way to scales with cation defects as the chromium content of the alloy is increased above 20 per cent. While at the critical composition of 3 mole per cent ferric oxide the two types of defect may balance, the greater mobility of the cation vacancies may result in the flux of this species predominating to higher iron con-This proposed change in ionic transport mechanism will have important consequences on the integrity and adhesion of the oxide scales formed. Our preliminary measurements have indicated lower compressive stresses in oxides grown on pure chromium and on a 50 per cent chromium/50 per cent iron alloy than in the oxide forming on the 28 per cent chromium/iron alloy, in broad agreement with recent qualitative observations by Caplan and Cohen¹². These measurements have already been used by Noden et al.22 to explain their observations of the growth of fuel element cans during oxidation in carbon dioxide and oxygen. The predominating ionic transport mechanism will probably vary as the oxidation proceeds, for it is known that the oxide composition changes during growth.

We thank Mr F. Hicks for preparing some of the chromium oxide-ferric oxide specimens and Mr W. B. A. Sharp and Dr V. R. Howes for discussion and for their contributions to the whole oxidation programme.

MOLECULAR STRUCTURE

Distribution of an Arginine-Lysine Interchange in the Invariable Half of Human L-Type Bence-Jones Proteins

SEROLOGICAL reagents have been used to identify allelic antigenic determinants of the peptide chains of immunoglobulins1. Several allotypic determinants of the heavy chains of human immunoglobulins have been identified2 and their distribution in human populations3 has been investigated. Only a few allotypic determinants of the K-type light chain of human immunoglobulins have been identified2 and one of these has been correlated with an amino-acid interchange in the invariable half of these peptide chains4-6. No homologous serological reagent has been available for the study of the L-type light chain.

Ein and Fahey' described a heterologous antiserum, obtained from the rabbit, which is valuable for identifying two sub-types of L-type human light chains. These subtype determinants, designated Oz(+) and Oz(-) respectively, were found to be present in Bence-Jones proteins and in all types of myeloma proteins tested, as well as in pooled immunoglobulins7. Appella and Ein8 have correlated the Oz antigenic type of 12 L-type Bence-Jones proteins with an amino-acid interchange in the invariable COOH-terminal sequence of these proteins. proteins were shown to have lysine, whereas Oz(-) proteins had arginine at position 190 (ref. 8).

We have studied the distribution of the arginine or lysine residue at position 190 in several L-type Bence-Jones proteins. The relative frequency of this aminoacid interchange presumably reflects the relative frequency of the corresponding allotypic determinants. present investigation has thus provided some information on the relative gene frequency of these determinants, which, although direct genetic analysis is still lacking, may be thought to be allelic.

Forty Bence-Jones proteins of type L have been examined for the presence of arginine or lysine at position 190. The proteins were obtained from the sources described before¹⁰. The proteins were isolated, purified, aminoethylated and digested with trypsin, also as previously described10. The analytical methods used before to obtain peptide maps of Bence-Jones proteins10 failed to separate clearly the tripeptides Ser-His-Lys and Ser-His-Arg which are obtained by tryptic digestion from the two sub-types of L-type Bence-Jones proteins, respectively, and which correspond to residues 188-190 (ref. 11). Furthermore, free arginine, which is sometimes present in the tryptic digest of Bence-Jones proteins, overlaps in part with these tripeptides.

The tryptic digest of Bence-Jones proteins was analysed by high voltage ionophoresis at pH 4.7 (ref. 12) and the ionograms were stained with ninhydrin and with reagents specific for arginine and histidine¹⁰. There was clear separation of a peptide positive for histidine and arginine from a peptide positive for histidine only (Fig. 1). All the Bence-Jones proteins analysed contained either peptide. The peptides were eluted from the ionograms, hydrolysed and their amino-acid composition was analysed¹¹. Ser-His-Arg and Ser-His-Lys, respectively,

Of the forty proteins analysed thirty-five had arginine in position 190 and five had lysine. The relative frequency of the allotypic determinants corresponding to these amino-acid residues is thus presumably close to 87.5 per cent and 12.5 per cent, respectively.

Appella and Ein⁸ have reported that of twelve proteins examined seven had lysine and five had arginine at position 190. The relative frequency of these amino-acid residues corresponded well with the relative frequency of Oz(+) and Oz(-) proteins in a sample of 22 L-type proteins7; twelve of these (55 per cent) were found to be

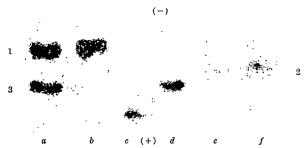

Fig. 1. Ionophoresis at pH+7 (ref. 12) of the tryptic digests of Bence-Jones proteins. Only that area of the ionophoresis where the most positively charged peptides and amino-acids run is shown. a and b, Digests of Bence-Jones proteins 1 and 69; e and f, digests of Bence-Jones proteins 87 and 134; e, 0-02 μ moles of arginine; and d, 0-02 μ moles of histidine. The lonophoresis was run at 5 kV for 1 h and 40 min on a 1 m strip of paper. The paper was stained with ninhydrin, and the peptides were eluted and analysed. 1 contains Ser-His-Lys; 2 contains Ser-His-Arg; 3 is a peptide which contains neither histidine nor arginine.

Oz(+), while 10 (45 per cent) were Oz(-). The relative frequency of the two sub-types of L-type chains, however, was different in a sample of twenty-two myeloma proteins. Of these eight (36 per cent) were Oz(+) and fourteen (64 per cent) were Oz(-).

The relative frequency of arginine and lysine at position 190 in the large sample of Bence-Jones proteins which we examined is quite different from that found by Appella and Eins. A possible explanation for this discrepancy is that the small sample of Bence-Jones proteins examined by Appella and Ein is not representative, although it seems unlikely that such a difference in the relative frequency of the two sub-types of Bence-Jones proteins can be explained by a sampling bias. Another explanation is that the Bence-Jones proteins were obtained from human populations differing in the relative frequency of the two sub-types. The Bence-Jones proteins analysed by us came from many countries 10 and it is impossible to establish any correlation with a given human population.

The relative frequency of valine/leucine at position 191 in Bence-Jones proteins of type K parallels the gene frequency Inv(a-)/Inv(a+) (ref. 5). The frequency of arginine/lysine at position 190 of Bence-Jones proteins of type L is similar to that of valine/leucine of K-type proteins, and so we might expect that the relative frequency of the corresponding genes is also similar to that of the Inv(a) genes.

CHEMISTRY

Effect of an Applied Electrical Field on the Gamma-radiolysis of Gaseous Hydrogen Chloride

Previous publications¹⁻³ on the gamma-radiolysis of hydrogen chloride gas provide evidence for the presence of two hydrogen forming species. One of these is termed

a "hot" hydrogen atom and may be due to the excitation process

$$HCl \longrightarrow HCl^* \longrightarrow H^* + Cl$$
 (1)

where * denotes an excited species. The other, referred to as a "thermal" hydrogen atom, may or may not have a The initial ionizing thermalized electron as its precursor. action should produce both excited HCl molecules (reaction (1)) and HCl+ ions along with electrons

$$HCl \longrightarrow HCl^+ + e$$
 (2)

In the hope of interpreting the subsequent reactions of the ions produced in reaction (2), a study of the effect of an applied electrical field during radiolysis was carried out. A 'Pyrex' cylindrical glass cell which had its parallel end faces coated with colloidal graphite was used. Before the cell was filled with hydrogen chloride, it was baked out overnight at 150° C and evacuated for several hours to a pressure of 10-6 cm mercury. The faces were connected through the glass by platinum leads and served as the electrodes. The applied potential across the electrodes was supplied by a Hamner model N-413 high voltage power supply. A Keithley 410C micro-microammeter was used to measure the current. Both these instruments were connected to the irradiation cell by coaxial cables. Pressures of hydrogen chloride gas ranged from 150 to 700 torr and a field gradient from 0 to 6 V/cm/torr was applied. The samples were irradiated with a 1,200 c. cobalt-60 source.

Fig. I shows plots of ion pair yield of hydrogen production against applied field, and ionization current against applied field. It can be readily seen from these plots that the applied electrical field has no effect on the production of hydrogen either in the ion recombination region or in the saturation region for the range of the applied field investigated. This can be interpreted to mean that ion recombination reactions play an unimportant part in the formation of hydrogen4.

At this point the possible reactions of the electrons produced in reaction (2) will be considered. electrons should rapidly become thermalized and disappear by any of the following processes: ambipolar diffusion to the walls of the vessel; ion-electron recombination; and attachment to neutral molecules to form negative ions.

The first order decay constant for electron-ion loss by ambipolar diffusion is given by D/Δ^2 where D is the ambipolar diffusion coefficient and Δ is a length characteristic of the vessel geometry. A typical value of D $(0.09 \text{ cm}^2/\text{sec} \text{ at 1 atm.})$ (ref. 5) and $\Delta(\sim 1 \text{ cm})$ for the system used leads to $D/\Delta^2 = 70/P$ torr per sec This gives a diffusional loss time of at least I sec for pressures greater than 70 torr (1018 molecules/cc).

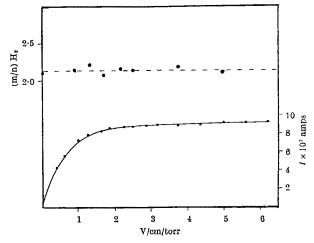

Fig. 1. Plots of ion pair yield of hydrogen production against applied field (dashed line) and ionization current against applied field (continuous line).

In these experiments, the rate of ion formation was about 10^{11} ions/cc/sec. If an ion electron recombination coefficient of 10-6 cc/sec is assumed6, then the calculated lifetime of the electron in this process is of the order of 10-3 sec.

The electron, on its way to becoming thermalized, can form Cl- ions by the ion pair formation process

$$e + HCl \longrightarrow H^+ + Cl^- + e$$
 (3)

or else may undergo the dissociative electron capture reaction

$$e + HCl \longrightarrow H + Cl^{-}$$
 (4)

The energy thresholds for these two processes are 14.5 and 0.6 eV (ref. 7), respectively. It has been shown that only about 5 per cent of the electrons will react by process (4) and that the capture cross-section for reaction (4) is at least one order of magnitude greater than that for the reaction (3) (ref. 3). Davidows has obtained evidence that the electrons disappear in a trimolecular reaction, the rate constant of which is in the range 2×10^{-32} cm⁶/ molecule²/sec. This gives a lifetime for the thermalized electron of the order of 10⁻⁸ sec at 600 torr pressure of hydrogen chloride. The three body processes, which could be depicted thus

should therefore be the principal process for electron dis-

Now the HCl+ ion can undergo charge neutralization by reacting either with an electron or the Cl- ion or else take part in the ion molecule reaction

$$HCl + HCl^+ \longrightarrow H_2Cl^+ + Cl$$
 (6)

This reaction has a specific rate constant of about 4×10^{-10} ce/molecule/sec (ref. 9). A lifetime of about 10^{-9} sec for the ion when the pressure of hydrogen chloride is about 700 torr (1019 molecules/cc) can be calculated. This is much faster than the ion recombination reaction and therefore the fate of the HCl+ ion would be chiefly to form the H₂Cl⁺ ion. This latter ion would be the cation collected on application of an electrical field.

The recent work of Kebarle et al.10 on ammonia and water has shown that the $\mathrm{NH_{4}^{+}}$ and $\mathrm{H_{3}O^{+}}$ ions are heavily clustered at atmospheric pressures. In view of this, clustering of the H2Cl+ and Cl- ions would be expected to occur, followed by a non-dissociative recombination of these clustered ions thus

$$H_2Cl^+_{(nHCl)} + Cl^-_{(mHCl)} \longrightarrow (n + m + 2)HCl$$
 (7)

This reaction is in agreement with previous evidence³ and is supported by the fact that there is no change in the ionic yield in the ion recombination region (Fig. 1) during the application of an electric field. Another explanation of the applied electric field results could be that reaction (7) produces hydrogen and that in the presence of the electric field the H₂Cl+ ions form H or H₂ on neutralization at the carbon electrodes. At present very little is known about reactions occurring at the electrodes in the gas phase and until more is known the first explanation of the results seems more acceptable.

At a field strength of 10 V/cm/torr, the effective electron energy in gaseous HCl is estimated at 0.14 eV (ref. 11). This energy is much too low to cause dissociation of the HCl molecule by either of the two processes below

$$e + HCl \longrightarrow H^+ + Cl^- + e$$
 (8)

$$e + HCl \longrightarrow HCl^* + e \longrightarrow H^* + Cl + e$$
 (9)

The first requires an energy of at least 14.5 eV and the second at least 4.5 eV. This means that a reduction of hydrogen yield caused by neutralization of ions at the electrodes cannot be compensated for by the processes described here.

BIOLOGY

Technique for rearing Marine Calanoid Copepods in Laboratory Conditions

Allen and Nelson¹, who succeeded in keeping several Calanus alive for a few weeks in laboratory conditions, stated that it should be possible to rear Calanus in the laboratory without difficulty. Since then it has become apparent that the marine calanoid copepods are hard to rear and breed in laboratory conditions, and Crawshay² has discussed some of the early difficulties. A. G. Nicholls (unpublished results) reared three adult female Calanus from eggs3, and Conover4 reared two adult female Calanus with considerable mortality. It is only recently, however, that marine calanoid copepods—Acartia tonsa Dana⁵ and Acartia clausi Giesbrecht⁶—have been bred through the first filial generation and beyond.

A simple laboratory technique for rearing calanoid copepods under laboratory conditions has been used in present investigations on the rate of development of copepods. Adults of Temora longicornis (O. F. Müller) and Pseudocalanus minutus (Krøyer) have been successfully reared from egg to adult for the first time, and Pseudocalanus stage 1 nauplii have been reared to copepodid 1 at about 0°, 3°, 7° and 12° C.

Adult female copepods were selected from plankton tows and placed in 30 ml. Petri dishes kept at 7° Recently hatched nauplii were transferred to 20 ml. vials which were filled with one-third fresh sea water and onethird Erdschreiber medium containing a unialgal culture of the marine crysomonad Isochrysis galbana Parke, which gave a final cell concentration of 300,000–600,000 cells/ml. The vials were placed in a water bath at $12^{\circ} \pm 0.01^{\circ}$ C and kept under continuous weak illumination. The vials were checked regularly and fresh algal medium was added periodically to maintain a dense concentration. The water in the vials was not changed throughout the duration of the experiment. Eleven adults of the two species have been reared with a mortality of between 50 and 70 per cent, most of the deaths occurring in the naupliar stages. In one experiment, six of the fourteen nauplii which died did so on the surface film of water, which suggests that mortality could be further decreased by increasing the volume to surface ratio in experimental cultures. A male and female of Temora were reared in one experiment; these adults were fertile, for they produced first filial generation nauplii. It has not been possible to determine whether the *Pseudocalanus* were capable of producing a first filial generation because only females have so far been reared. It was observed, however, that these females laid infertile eggs.

Previous work showed that although the adults of Pseudocalanus elongatus Boeck and Temora longicornis

could be kept successfully in the laboratory fed on a culture of Isochrysis galbana, the larval stages could not be so kept because successful moults could not be obtained. I have since found that the flagellate Isochrysis galbana is a suitable food for the first generation larval stages in these species. The temperature and illumination are not critical factors, for early larval stages of Pseudocalanus have been reared at temperatures from 0° to 12° C, and a few adults have been reared in the dark.

The success of this laboratory technique appears to result from one or more of the following conditions: the use of fresh sea water taken from the same area of the sea as the adults; the use and maintenance of a high concentration of Isochrysis galbana as food; and the use of a simple technique with minimal disturbance of the copepods by not changing the sea water in experiments. Oxygen Consumption of Ectoprocts

Mangum and Schopf¹ have reported oxygen consumption rates for a representative species of ectoproct, Bugula turrita. They found considerable discrepancy between their measured value and that predicted from a model they proposed based on ectoproct morphology. discrepancy led them to hypothesize that the rhythmic expansion and contraction of the tentacles of the animals was required as a circulatory mechanism to supply oxygen to the tissues.

Because of the small size of Bugula turrita, however, a hemi-cylinder 0.16 mm in diameter and 0.6 mm long, it would be expected that sufficient oxygen could be obtained from the environment by a diffusion process alone. Here we treat the model proposed by Mangum and Schopf by

standard mathematical techniques as a diffusion system containing a chemical reaction, and show that the measured oxygen consumption rate can be completely accounted for by diffusion alone; no assumption of internal circulatory mechanisms is required. The model is shown in Fig. 1, a, b, c and d. The ectoprocts are divided into three parts for analysis. The body or zoecium has a flat base, composed of chitin reinforced with calcium carbonate, which is impermeable to oxygen. On this base three annular layers of epidermis, coelomic fluid and tissue, surround the core of coelomic fluid. Three concentric annuli surrounding a coelomic core are also proposed for the tentacle sheath. The fourteen tentacles are composed of a layer of epidermis cells surrounding a coelomic core.

In the present analysis it is assumed that the oxygen consumption takes place entirely in the tissue layers (see Fig. 1, b, c and d). No oxygen consumption takes place in the coelomic regions (clear regions in Fig. 1, b, c and d), which are primarily sea water. The whole animal oxygen consumption rate 4.5 × 10-4 µl./animal h, reported in ref. 1, was recalculated to be 4.87×10^{-7} g/cm³ soft tissue sec by assuming that all oxygen consumption was by soft tissue only. This oxygen consumption rate was then apportioned to the various soft tissue parts of the animal on the basis of the fractional volume of each part.

In cylindrical co-ordinates, the general steady-state diffusion equation can be written

$$D\left[\frac{\mathrm{d}^2 c}{\mathrm{d} r^2} + \frac{1}{r} \frac{\mathrm{d}c}{\mathrm{d}r}\right] - Q = 0 \tag{1}$$

where D is the diffusivity of oxygen in cm²/sec; c is the concentration of oxygen in g/cm^3 ; r is the distance from the axis of the cylinder in cm; and Q is the oxygen consumption rate in g/cm³ sec.

The oxygen concentration is more conveniently expressed as an oxygen tension through the Henry's law equation

$$c = kp \tag{2}$$

c = kp (2) where k is the Henry's law constant in g/cm³ mm mercury, and p is the oxygen tension in mm mercury. Substitution of equation (2) into equation (1) gives

$$\frac{\mathrm{d}^2 p}{\mathrm{d} r^2} + \frac{1}{r} \frac{\mathrm{d} p}{\mathrm{d} r} - \frac{Q}{D k} = 0 \tag{3}$$

Diffusion in the axial direction is neglected. If axial diffusion were to be included it would increase the delivery of oxygen by diffusion, thereby strengthening the argument for diffusion as the sole transport process

To obtain the general solution of equation (3) we let R=r/a, where a= maximum radius of a particular part of the ectoproct, and let $P=p-p_0$, where p_0 is the oxygon tension in sea water. Using standard methods of solving equidimensional linear differential equations2 the general form of the solution is

$$P = A \log R + B + \frac{Qa^2}{4Dk} R^2 \tag{4}$$

Equation (4) is applicable to each of the layers in the three parts. To evaluate the unknown constants A and B, for each particular region, the following boundary conditions are imposed. (i) At the outer surface of the ectoproct the oxygen tension is assumed equal to the equilibrium concentration of oxygen in sea water; that is,

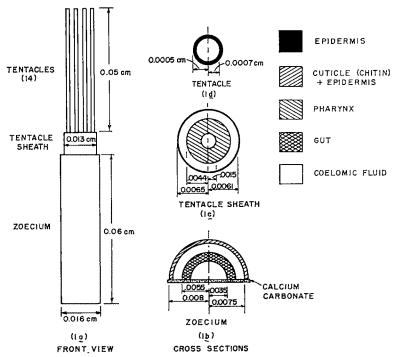

Fig. 1. Diagrammatic representation of morphology of Bugula turrita.

	Table 1	
Parameter	Value	Ref.
Diffusivity of oxygen through water	$1.8 \times 10^{-5} \text{ cm}^2 \text{ sec}^{-1}$	3
Diffusivity of oxygen through tissue	0.5×10^{-5} cm ² sec ⁻¹	4
Diffusivity of oxygen through chitin and epidermis	$3.0 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$	4
Henry's law constant	4.7×10^{-8} g/cc mm mercury	5
Equilibrium concentration of oxygen in sea water	7.4×10^{-6} g/cc (155 mm mercury oxygen pressure)	5
Oxygen consumption rate in soft tissue	4.87×10^{-7} g/cm ³ tissue sec	1

R=1, P=0. This boundary condition implies that the resistance to oxygen transfer in the sea water is small enough to be neglected. In view of the relatively high resistance in the outer layer of the animal, and since ectoprocts are usually found in well-aerated regions near the surface of the water, this appears to be a reasonable assumption. (ii) At steady state, the flux of material into the interior core of sea water is zero (for all three parts); that is, at the boundary, (dP/dR) = 0. This condition is easily visualized by noting that because there is no consumption in the interior core of sea water the core will, at the steady-state, take on a uniform oxygen tension. Under this condition there is no oxygen tension gradient in the core, including at the core-interior wall boundary. (iii) The remaining boundary conditions are provided by continuity requirements at the interfaces between the various regions. The mass flux and the tension must be equal on both sides of all interfaces. For example, the tension and mass flux at the outer surface of the zoecium gut tissue must be equal to the flux and tension at the inner surface of the coelomic annulus.

Using these boundary conditions the values of A and Bin equation (4) can be obtained for the different regions (remembering that Q=0 for all coelomic sections).

The concentration profiles for the zoecium and tentacle sheath obtained from these solutions are shown in Figs. 2 and 3, using the values of D, Q and p_0 shown in Table 1.

It can be seen in the figures that the minimum oxygen tension never drops below 93 per cent of the bulk value. This value is well above the minimum required for the health of the animal. The profile for the tentacles never drops below 99.9 per cent of bulk value, so it is not shown.

There are two principal differences between our approach and that of Mangum and Schopf: (i) they did not take the individual regions into account but instead averaged the physical properties and consumption rates over each part of the animal, thereby eliminating any meaningful concentration profiles; (ii) the relations developed by

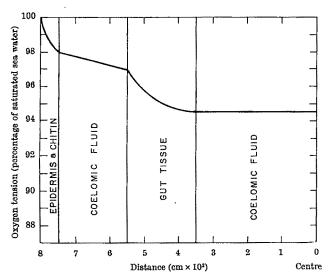

Fig. 2. Oxygen tension profile through the zoecium.

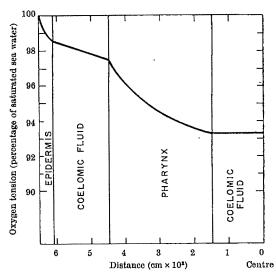

Fig. 3. Oxygen tension profile through the tentacle sheath.

Gerard', which they used for their calculations, result from incorrect applications of a boundary condition.

These differences in approach lead to the difference between their conclusion and ours. We conclude that the ectoproct is completely supplied with oxygen by a diffusion process.

Effect of 5Bs in suppressing the Expression of Altered Dosage of 5B^L on Meiotic Chromosome Pairing in Triticum destivum

CHROMOSOME 5B of the allohexaploid wheat, Triticum aestivum (2n=42), carries out a genetic activity that results in the suppression of synapsis at meiosis between homoeologous chromosomes of different genomes1,2. Synapsis, however, still occurs between fully homologous partner chromosomes despite the 5B activity, which therefore narrows the specificity of meiotic chromosome pairing.

Chromosome 5B is markedly heterobrachial and the suppression of homoeologous pairing depends on an activity of the long arm $(5B^L)$ alone². In the presence of the short arm $(5B^{8})$, but in the absence of the long arms, homoeologous synapsis occurs as it does in the absence of the complete chromosome. By contrast there is no homoeologous synapsis if $5B^L$ is present but $5B^S$ absent³.

Initially it was thought that the activity could only be recognized when genotypes were compared in which chromosome 5B was either present or absent. Homoeologous pairing was, for example, observed to occur in 40-chromosome 5B nullisomics but not in 41-chromosome 5B monosomics or in 42-chromosome euploids. Increases in dosage of the chromosome above the monosomic level apparently did not give rise to any change in the nature or extent of synapsis once homoeologous synapsis was

suppressed.

Feldman, however, demonstrated that increased dosage of $5B^L$ —in the absence of $5B^S$ —in plants with two and three $5B^L$ isochromosomes, greatly reduced the frequencies of chiasmata formed between homologues, and also caused other abnormalities of synapsis4. This was attributed to the expression in increased dosages of the gene on $5B^L$ responsible for the prevention of homoeologous synapsis in monosomics and euploids. Riley et al. confirmed the lower chiasma frequencies of plants disomic for the $5B^L$ isochromosome and lacking $5B^{\frac{1}{2}}$, but directed attention to the contrast between these plants and those tetrasomic for the complete chromosome 5B in which there was normal synapsis. The chief distinction between these genotypes was in the presence or absence of $5B^{\circ}$; one possible explanation for its cause was that $5B^{\circ}$ has a genetic activity that influences synapsis in the reverse direction from that of $5B^{L}$. The work described here was intended to test this possibility.

All the observations were carried out on derivatives of the variety 'Chinese Spring' of T. aestivum. The forms used had a range of doses of $5B^{L}$ in the presence and in the absence of $5B^{S}$. They were: (a) 42- and 44-chromosome plants with the complete chromosome 5B in the disomic (euploid) or tetrasomic (tetra 5B) conditions, respectively; (b) 41- and 42-chromosome plants, respectively mono- or disomic for the $5B^{L}$ isochromosome and lacking $5B^{S}$ (mono- and di-iso $5B^{L}$); (c) 42-, 43- and 44-chromosome plants respectively, di-, tri- and tetrasomic for the $5B^{L}$ telocentric (di-, tri- and tetra-telo $5B^{L}$). Tri- and tetra-telo $5B^{L}$ forms were extracted by Selection from the standard di-telo $5B^{L}$ line; (d) 43-chromosome plants simultaneously disomic for complete chromosome 5B and mono-iso $5B^{L}$.

Plants of all these genotypes were grown in controlled environment rooms at 15° C and at 20° C under continuous light. Preparations were made of anthers with pollen mother cells at first metaphase of meiosis, and the numbers of chiasmata were scored in twenty cells of every plant in the experiment. The means of these scores are recorded in Table 1, expressed as chiasmata/chromosome. This form of presentation is used to avoid the effects of differences of chromosome number between some genotypes. In arriving at the means each isochromosome was regarded as two chromosomes because it was capable of forming chiasmata interbrachially with itself and where such chiasmata occurred they were included in the total for the cell.

From these observations it is clear that increases in the dosage of $5B^L$, over the range from two to four, lead to marked reductions in chiasma frequencies irrespective of whether $5B^{\nu}$ is represented by telocentrics or by isochromosomes. By contrast, there is little difference between the chiasma frequencies of plants with two or four doses of $5B^{\nu}$ when 5B is also present, for example,

Table 1. Mean chiasmata/ohromosome at 15° c and 20° c in plants with various doses of the long arm $(5B^s)$ and the short arm $(5B^s)$ of chromosome 5B of T. activum (twenty cells per plant)

a ,	5B de		Chiasmata/chromosome		
Genotype	Long arm	Short arm	15° C	20° C

Euploid Disome complete 5B	2	2	$1 \cdot 137 \pm 0 \cdot 018$	1·101 ± 0·009	
+ mono-iso 5BL	4	2	1.025 ± 0.009	0.987 ± 0.014	
Tetra 5B	4	4	1.051 ± 0.009	0.974 ± 0.009	

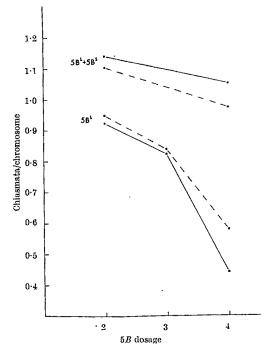

Fig. 1. The mean chiasmata/chromosome at each dose level of the entire chromosome 5B ($5B^L + 5B^S$) and of the long arm alone ($5B^L$) at 15° C (——) and 20° C (———).

when euploid and tetra 5B genotypes are compared. In addition, plants disomic for the complete chromosome and simultaneously mono-iso $5B^L$, that is, with four $5B^L$ and two $5B^S$, had frequencies like those of tetra 5B plants at the same temperature.

These data, which are summarized in Fig. 1, confirm that $5B^s$ carries out a genetic activity that influences meiotic chromosome pairing and that its effect on pairing is the reverse of that of $5B^t$. This activity of $5B^s$ therefore increases the extent of synapsis, and is capable of suppressing the expression of increased dosage of $5B^t$ because only in its absence is chiasma frequency modified by changed dosage of $5B^t$. There is also a suggestion that a $5B^s$ activity modifies the response of chiasma frequency to temperature differences. The lower frequencies occurred at the lower temperature in the absence, but at the higher temperature in the presence, of $5B^s$.

On the assumption that the $5B^{L}$ dose effect on chiasma frequency is a manifestation of modified synapsis and that it results from the operation of the same system by which homoeologous synapsis is also inhibited, the present results are consistent with the causal hypothesis proposed by Feldman4. This asserts that the 5BL activity affects the presynaptic spatial distribution, and relative orientation, of homologous and homoeologous chromosomes. The presence of $5B^L$ in a single dose leads to the greater separation of homoeologues than homologues and so to the prevention of homoeologous synapsis. increases in the dosage of $5B^{t}$ lead to progressively greater separation even between homologues and so to overall reduction on the amount of synapsis. If these ideas about $5B^L$ effects are correct, then it must be proposed $5B^s$ also influences the relative positions and orientations of chromosomes.

As with other recent work, these interpretations of the present results on a spatial model demand that the nucleus is regarded as having a quite precise internal organization in which the relative positions of chromosomes and of unlinked chromosomal segments are specifically ordered. From the 5B system of wheat it appears that there may be gene products which determine the spatial relationships of chromosomes.

Finally, it is worth while considering the practical implications of the recognition of the $5B^s$ activity. Knowledge of the effect of $5B^{L}$ on synapsis has been used in practical breeding work aimed at producing improved genotypes in the wheat crop by homoeologous recombination. The present observations suggest that the maximum amount of homoeologous pairing and recombination will occur when the $5B^L$ activity is removed or suppressed but the $5B^3$ activity is unimpaired.

CYTOLOGY

Transformation of Polyploid Hamster Cells by Polyoma Virus

THERE is a degree of genetic heterogeneity for susceptibility to transformation by polyoma virus in the hamster cell line BHK21-13 (refs. 1 and 2) and we have shown³ variations in susceptibility to transformation related to the position of the cell in its life cycle. Our results are compatible with the hypothesis that increased susceptibility is related to the doubling of the cell's genome before division, and so a difference in ploidy could account for the genetic heterogeneity as well. In fact, chromosome preparations of BHK21 cells, although predominantly diploid (forty-four chromosomes), show a minor proportion of metaphases in the tetraploid range (up to 10 per cent), and pure lines with a higher proportion (up to 100 per cent) of such "tetraploid" cells can be isolated. (The terms "diploid" and "tetraploid" will be used here to define cell lines showing frequency distributions of chromosome numbers with a mode = 44 ± 2 or 88 ± 4 , respectively.)

We have described elsewhere³ the general culture methods and techniques related to the assay of polyoma virus infection and transformation. The transformation frequency was calculated as the percentage of infected cells that would develop into macroscopic colonies in a soft agar medium4. No correction was made for colonies that would develop from uninfected controls, because all sub-lines in which background colony growth would exceed 2-3 per cent of infected were discarded.

Clonal isolation of individual sub-lines was carried out according to the method of Puck et al.5. Chromosome preparations were made according to the technique of Moorhead et al.8 with minor modifications. Chromosome counts were performed on a random sample of 50-100 metaphase plates/cell line.

Three lines yielding high percentages of viable polyploid cells were isolated after repeated cloning, and will be referred to as 2P3, 2P4 and P108. From each of these lines, a number of almost pure "diploid" and "tetraploid" clones was selected. Infection with polyoma virus showed all these clones to be transformable. Transformation tests were carried out as soon as each clone had developed into a sizable cell population, to keep any acquired variability among sister clones to a minimum.

Table 1 summarizes the data from four independent cell lineages. Transformation tests for each individual sub-line belonging to the same family were carried out in

* Two hundred cells/6 mm Petri dish were plated in ordinary fluid medium (eight dishes per point).
† Multiplicity of infection: 400 PFU/cell. Five or ten thousand infected cells/6 mm Petri dish were plated in soft agar medium (five dishes per point).

the same experiment. In some experiments, the parental BHK21 cell line was included as a control. It can be seen that transformation frequencies, as well as plating efficiencies in ordinary fluid medium, vary widely. Within each family a positive correlation was found between plating efficiency and transformation frequency (Fig. 1), which indicates that polyoma infection cannot induce multiplication in cells that would not otherwise develop into macroscopic colonies. For this reason transformation frequencies were corrected for plating efficiency for comparison with each other.

Experiments 1, 2 and 3 refer to three groups of sister sub-lines. Each sub-line was isolated by single-cell cloning from the high-polyploid lines 2P3, 2P4 and P108. Transformation frequencies in clones of line P108 are consistently lower than those in line 2P3. Experiment 4 refers to a polyploid clone (Hy3) obtained by growing in the presence of 10^{-5} molar aminopterin, 10^{-5} molar glycine, 4×10^{-5} molar thymidine and 10^{-4} molar hypoxanthine a

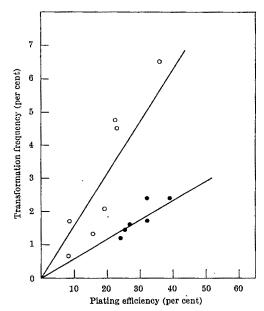

Fig. 1. Relationship between plating efficiency in fluid medium, and transformation frequency, determined as the percentage of infected cells (400 FFU/cell) that would give rise to visible colonies in soft agar medium. O, 2P3 sub-lines; •• , P108 sub-lines. Same data as those reported in Table 1.

mixed culture of two variant BHK21 sub-lines, B1 and T6, respectively, lacking thymidine kinase and inosinic acid pyrophosphorylase. (The hybrid line was kindly provided by J. W. Littlefield.) Hy3 was therefore selected for its ability to grow in a medium that required TDRkinase as well as IMP-pyrophosphorylase activity for a cell to survive. This method has been devised for the selection of somatic cell hybrids?. The modal chromosome number of Hy3 is approximately the sum of the modal values of B1 and T6. Although no chromosome markers were available to substantiate its hybrid nature, both its phenotype and its karyotype strongly suggest that Hy3 arose by fusion of B1 and T6. For this reason it was interesting to compare the transformation rate of Hy3 with that of its "parental" lines B1 and T6.

From the tabulated data it appears that in experiments 1 and 3 no consistent difference is observed between "tetraploids" and "diploids". In experiment 2, some of the "tetraploid" sub-lines show transformation frequencies lower than those of closely related "diploid" sub-lines. There is thus variation in the transforma-

tion frequencies of various "tetraploids" in comparison with "diploids", but this variation is not consistent and cannot explain the genetic heterogeneity for susceptibility to transformation which others have found. Furthermore, in no case is the difference high enough to suggest a "two-hit" phenomenon, which would be expected if each of the parental chromosome complements had to be "transformed" independently. For example, in the case of the hybrid line Hy3 (Table 1, experiment 4), if both parental genotypes had to be "transformed" for the hybrid to show a transformed phenotype, the expected frequency of transformation would be approximately $0.08 \times 0.04 = 0.0032$ —that is, about ten times lower than the frequency observed. The fact that the tumour-specific antigens and the polyoma-specific transplantation antigens present in transformed mouse cells can still be demonstrated in somatic hybrids between these cells and normal mouse cells8,9 also suggests that transformation need have occurred in but one partner of the hybrid.

Twin Spots as Evidence for Mitotic Crossing-over in Aspergillus induced by Ultra-violet Light

SOMATIC crossing-over was first described by Stern¹, who showed that twin spots of mutant cells occurring on the abdomen of a Drosophila were produced by crossing-over at the four strand stage of mitosis.

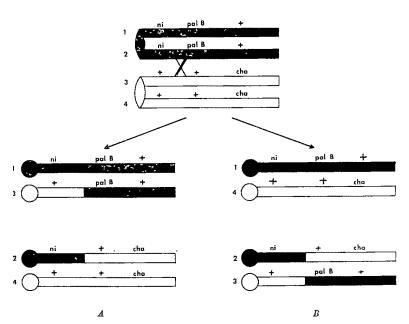

Fig. 1. Diploid 1: ni(50), nitrite requiring; palB(7), lacking alkaline phosphatase; cha(1), chartreuse conidial colour.

After the artificial production of diploids of the fungus Aspergillus, it was found that mitotic segregation resulted in the formation of homozygous, diploid segregants of mutant colour, seen as a single or a group of conidial heads in an otherwise heterozygous, parental, green colony². These segregants were believed to arise as a consequence of mitotic crossing-over3, and supporting evidence was obtained by Roper and Pritchards. Using selective techniques they reported the recovery, in a single nucleus, of the two reciprocal products of mitotic crossing-over within the ad8 cistron. The spontaneous occurrence of "twin colonies" consisting solely of the two segregants expected in twin spots was reported by Käfer⁷, thus providing evidence for a reciprocal four strand mechanism of intergenic mitotic crossing-over, as in Drosophila. Only one such twin colony, resulting from mitotic crossing-over in chromosome VIII, was observed after plating about 10,000 spores on a non-selective complete medium, indicating that spontaneous twin colonies are rare.

We have developed two diploid strains of Aspergillus, where the arrangement of markers is such that both reciprocal products of mitotic crossing-over in chromosome VIII may be phenotypically distinguished in the twin colonies produced. One of these diploids is shown in Fig. 1 together with the two possible results of normal mitotic segregation following a crossing-over between the ni and palB loci. In case A one parental and one cross-over strand segregate into each of the two daughter nuclei, producing two reciprocal segregants, each homozygous for all markers distal to the point of crossing over. The occurrence of such an event in an initial division of a germinating spore will produce a twin colony. In case B one parental nucleus and one recombinant nucleus are produced, the latter containing both cross-over strands and being phenotypically indistinguishable from the parental diploid, for it remains heterozygous. The previously mentioned segregant4 was of this type.

Both diploids have been used to study mitotic recombination induced by ultra-violet light. Up to 5 per cent of surviving conidia produce twin colonies (Figs. 2 and 3) when germinating conidia are irradiated with ultraviolet light (10-15 per cent survival). The recovery of both reciprocal products in twin colonies provides conclusive evidence that ultra-violet irradiation induces mitotic crossing-over in Aspergillus. Because analogous twin colonies have previously been observed following ultra-

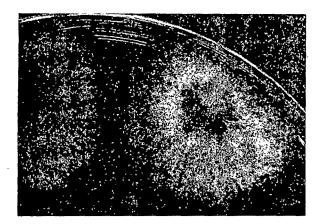

Fig. 2. Parental colony and twin colony induced in diploid 1. The parental is dark green while the twin colony is partly chartreuse and partly lacking alkaline phosphatase (these cells form a small dark brown area in the centre of the chartreuse colony due to their slower growth rate).

Fig. 3. Parental colony and twin colony induced in a bge-cha repulsion diploid. The parental colony is dark green while the twin colony is half chartreuse (light green) and half beige (bge is located proximal to ni, on the same chromosome arm)—probably allelic to fawn (Clutterbuck, personal communication).

violet irradiation of yeast⁸ and ustilago⁹, this effect of ultra-violet light on recombination may be a general phenomenon. These diploids provide a simple visual screening system for agents that may induce crossing-over.

This work was supported by a grant from the National Research Council of Canada. The ni, palB strain was kindly supplied by Dr G. Dorn.

Growth of Cell-strains and Primary Cells on Micro-carriers in Homogeneous Culture

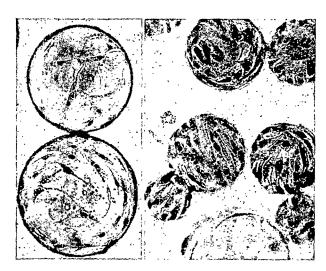

THERE are obvious advantages in culturing tissue cells in suspension instead of in monolayers and in using the suspension as a substrate for virus multiplication. Culture conditions for cell growth and virus multiplica-

tion can be studied and large scale production can be achieved more easily. The growth of cells from celllines, in suspension culture, as separate units or small clumps, has already been demonstrated. In contrast, nobody has yet succeeded in growing diploid and primary cells by this method^{1,2}, for the cells have become aneuploid or did not grow at all in suspension culture3.

Our own experiments with human diploid cells and with primary cells have confirmed earlier findings. essential difference between suspension and monolayer culture seems to be in the attachment of the cells to a solid surface in the latter method. If the wall of the monolayer vessel could be replaced by microscopic particles to serve as a surface for attachment, the advantages of homogeneous culture could be afforded to diploid cells. The suspended particles with cells need be no larger than the small clumps found in suspension culture of some cell-lines.

When looking for a suitable material to function as what we have termed "micro-carriers", we had to discount glass beads because these are too heavy to be kept in suspension. Dextran particles of the 'Sephadex' type do not have this disadvantage, but cells appeared to adhere and grow on these only if positively charged 'DEAE-Sephadex' is used. This was not unexpected, for tissue cells are negatively charged4.

Fully covered micro-carriers were obtained. About 20 h after inoculation the cells adhered to the 'Sephadex', a few on each particle, and gradually a confluent monolayer was formed. When the 'Sephadex' particles were fully covered some particles were joined together by a bridge of cells (Fig. 1).

Adhesion and growth of H cells on 'DEAE-Sephadex A-50' (\times 60). Left, after \pm 24 h; and right, after \pm 96 h.

By this method we successfully cultivated different cell-lines and also human diploid cells and primary rabbit kidney cells. Most experiments were carried out using fibroblast-like cells derived from embryonic rabbit skin (H cells) and diploid human embryonic lung cells (HEL cells). Neither grew in normal homogeneous culture.

The medium used for monolayer and homogeneous

culture was Eagle's minimum essential medium⁵, supplemented with 10 per cent newborn calf serum, 0.12 per cent 'Methocel' (15 c.p.s., Dow) and streptomycin and neomycin. To the medium for homogeneous culture 1 g/l. of sterile 'DEAE-Sephadex A-50' was added as a micro-carrier for the cells. Before being sterilized the 'Sephadex' was washed according to the standard washing procedure and equilibrated with phosphate buffered saline.

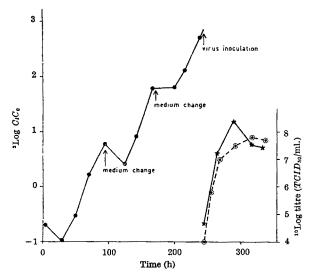

Fig. 2. Growth of HEL cells on micro-carriers in homogeneous culture and polio virus multiplication in these cells in comparison with that in cells from monolayers. The culture volume was at the start 1·5 l. and after changes in the medium 3·01.; the speed of the stirrer was 100 r.p.m., and the arbitrary C_0 is 1×10^3 cells/ml. \bullet —0, Cell concentration (calculated on 1·5 l. volume); \times — \times , virus titre homogeneous culture; \bigcirc --- \bigcirc , virus titre monolayer culture.

The Bilthoven unit⁶ was used for homogeneous culture. Culture conditions were the same as for the suspension cultures of cells from cell-lines, except that the speed of stirring was reduced. The homogeneous cultures were inoculated with trypsinized cells from monolayer cultures at an initial count of 50-100 × 103 cells/ml. The cell concentration was determined by counting nuclei in a Fuchs-Rosenthal counting chamber after staining with 0.5 per cent crystal violet in 0.1 molar citric acid. In this way the nuclei were freed from the 'Sephadex'.

The maximum growth rate of the cells in the microcarrier cultures was about the same as in monolayer cultures, but higher cell concentrations could be achieved by changing the medium. This was done by siphoning off the culture fluid after allowing the 'Sephadex' to settle. Fig. 2 also shows that as far as virus multiplication is concerned there was no essential difference between monolaver and micro-carrier culture. The optimal conditions for culturing cells and viruses by this culture method have still to be found.

Haematopoietic Stem Cells: Evidence for Competing Proliferative Demands

A HAEMATOPOIETIC stem cell must be able both to replicate itself and to differentiate into a formed blood element. The presence of a pool of multipotent, functionally important, common stem cells for the various haematopoietic formed elements has not as yet been established. There is evidence to suggest that there is a population of bone

marrow cells which when transplanted into irradiated recipients is capable of differentiating into more than one mature cellular form1-3. We are interested in whether this class of cells is functionally important, and specifically whether demand for one blood element limits the ability of the animal to produce other cell types. Such a relationship would suggest competitive demands on a common stem cell pool. There is some evidence to suggest that this may be the case. Harris et al.4 have shown that after large acute haemorrhage the number of granulocyte precursors in the guinea-pig bone marrow is reduced. The present experiment demonstrates that an increased demand for red blood cell production reduces the ability of transplanted syngeneic bone marrow to make granulocytic progeny.

A technique for assaying the granulocytic progeny of transplanted bone marrow has recently been developed. In this technique, syngeneic bone marrow is injected into lethally irradiated mice. The bone marrow is allowed to proliferate for 7-9 days in the recipient animal and its granulocytic progeny is then determined by measuring the peripheral granulocyte response to endotoxin. response has been shown to be a measure of the marrow granulocyte reserve. The greatest response to endotoxin is proportional to the number of marrow cells injected 7 days earlier and can be used to assay the proliferative capacity of such injected cells to produce mature granulo-

cytic progeny.

In this experiment, male C3H/HEJ mice 8-12 weeks old were used. They were divided into two groups, and one group was bled of 0.6 ml. from the orbital sinus 3 days and again 1 day before irradiation. Both groups of animals then received 700 r. whole body irradiation delivered with a 250 kV X-ray machine (HVL 1.65 mm³, FSD 50 cm) at 119 r./min. Each group was then subdivided and graded doses of syngeneic normal bone marrow were injected intravenously. One week later the animals were intravenously injected with 10-2 μg of 'Pyrexal', a purified lipopolysaccharide of Salmonella abortus equi, and the white blood cell counts recorded immediately before, and at 2, 4 and 6 h after, endotoxin. This response is essentially a granulocyte response and thus white blood counts are used, which obviates the need for differential counts. Haematocrits were measured before radiation and again on the day before administration of endotoxin. All blood samples were taken and injections were made by way of the mouse tail vein.

Table 1

Group	Haematocrit before X-ray	Haematocrit on day 6, 1 day before endotoxin
1 (700 r., no bleeding) (a) 0 bone marrow cells (b) 1.0×10^6 bone marrow cells (c) 20×10^6 bone marrow cells (d) 4.0×10^6 bone marrow cells	46·0 (±1·1) 45·8 (±1·2) 44·0 (±0·0) 43·3 (±0·6)	37·2 (±1·1) 41·2 (±1·6) 37·6 (±0·7) 40·2 (±1·0)
2 (700 τ ., bled twice of 0.6 ml.) (a) 0 bone marrow cells (b) 1.0×10^4 bone marrow cells (c) 2.0×10^4 bone marrow cells (d) 4.0×10^4 bone marrow cells	27·4 (±0·6) 24·6 (±1·2) 25·6 (±1·3) 25·6 (±0·5)	25·4 (±1·9) 21·2 (±0·7) 23·4 (±0·9) 24·4 (±0·2)

Each subgroup contains five animals. The number in parenthesis is the standar l error of the mean.

Table 1 shows the groups used and their haematocrits before injection of bone marrow and on day 6 (the day before endotoxin). Fig. 1 shows the maximum white blood cell responses to endotoxin in both groups plotted against the number of bone marrow cells injected 7 days before. The anaemic recipient animals are less able to respond to endotoxin, which indicates that the same number of transplanted marrow cells give rise to fewer granulocytic progeny in the bled recipients.

We attempted to confirm this in a somewhat different manner. In this second type of experiment, erythropoietin derived from sheep treated with phenylhydrazine (supplied by Connaught Medical Research Laboratories,

Toronto) was used instead of bleeding to stimulate erythropoiesis. This agent is produced by anaemic animals and has been shown to increase production of erythrocytic precursors by the stem cell compartment⁷⁻⁹. Mice were given 700 r. whole body irradiation and then divided into two groups. Both groups were given varying doses of bone marrow cells, and 7 days later the progeny of the transplanted bone marrow was evaluated by the response to endotoxin. This is identical to the technique used with bled recipients. The animals, however, were not bled; instead, one group was given three units of erythropoietin daily on days 2, 3 and 4 after bone marrow transplantation. The response to endotoxin in these two groups of animals is shown in Fig. 2. The ability of the transplanted marrow to make granulocytes is reduced in those recipient animals receiving erythropoietin.

A number of investigators have studied the effects of bleeding and hypertransfusion on stem cells as measured by the spleen colony technique¹¹⁻¹⁴. One group indicates that plethora reduces the number of macroscopically visible erythropoietic colonies without an accompanying increase in granulocytic colonies. Microscopic examination, however, reveals that the number of erythrocytic colonies is not diminished but rather they are reduced in size¹³. Other investigators^{12,14} indicate some increase in the number of granulocytic colonies with plethoric animals. Results with the spleen colony system therefore differ with different investigators. The spleen colony technique is dissimilar to the present experiment, which measures the production of end cells and thus is related not only to colony number but also to colony size and the proportion of mature cells of the various types produced. The second difference is that this experiment measures the production of all the haemopoietic tissue while the colony method is concerned only with growth in the spleen.

In the present experiment using bleeding or exogenous erythropoietin, the transplanted bone marrow proliferates under conditions of increased stimulus for red blood cells. Under these conditions the production of granulocytic progeny is reduced. We take this as evidence of competition by the granulocytic and erythrocytic series for a common factor. It is conceivable that a small pool of a necessary nutrient is the limiting factor, but no such

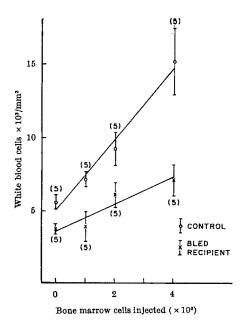

Fig. 1. Maximum white blood cell response to endotoxin plotted against bone marrow cells injected intravenously 7 days earlier. The mean and its standard error are plotted. The number in parenthesis is the number of animals used at each point. The statistical significance of the difference of the groups has a P>0.001 (ref. 10).

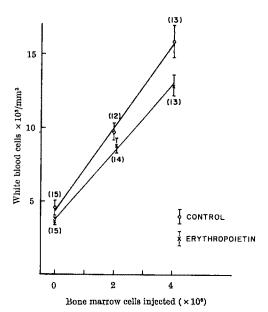

Fig. 2. Maximum white blood cell response to endotoxin plotted against bone marrow cells injected intravenously 7 days earlier. The mean and its standard error are plotted. The number in parenthesis is the number of animals used at each point. The statistical significance of the difference of the groups is 0.05 > P > 0.02 (ref. 10).

It seems more likely that these substance is known. experiments indicate competing proliferative demands on a pool of common stem cells. This implies a multipotent stem cell able to produce either erythrocytic or granulocytic progeny.

The experimental situation is such that there is a great demand for formed blood elements. The irradiated animals have a markedly reduced number of progenitor cells and the unirradiated, transfused stem cells are probably proliferating at maximum rate, because they must both repopulate the irradiated recipient with stem cells as well as differentiate to maintain a necessary level of peripheral blood cells. It is in this highly stressful situation that the interaction of proliferative demands can be demonstrated.

Lysosomes in Melanin Phagocytosis and Synthesis

THERE are two types of pigmented cells in normal human skin, the junctional dendritic melanocyte and the intradermal melanosome-phagocytosing melanophage (Fig. 1). In contrast to the melanocyte and its contained melanosome synthesizing process which have been thoroughly investigated, the cellular physiology of the melanophage remains unknown despite recent advances in electron microscopy and gradient biochemistry. The two cells containing melanin appear similar under the light microscope but electron microscopy reveals definite structural differences. The normal melanocyte contains various stages of melanosome synthesis occurring individually in close association with the Golgi apparatus. On the other hand, the actively phagocytosing melanophage concentrates its melanosomes 1-3 as degradative conglomerates into specially developed phagocytic vacuoles structurally resembling the lysosomes found in such tissues as kidney, liver and pancreas^{4,5}. Lysosomes were found to be rich in acid phosphatase^{4,5}, which predicted the presence of this hydrolytic enzyme in the phagocytic vacuoles of the dermal melanophage⁶. We found subsequently that acid phosphatase activity is concentrated in the melanophages and that there is little or no such activity in the melanocytes at the epidermal-dermal junction. On the other hand, the melanophages contain little if any tyrosinase while the junctional melanocytes are shown to contain an abundance of this oxidative enzyme, primarily within the premelanosomes. It is further observed with the electron microscope, using the modified Gomori reaction, that the electron opaque accumulation of lead sulphide resulting from acid phosphatase activity occurs primarily in the melanosome-concentrating phagocytic vacuoles of the melanophages7.

Although normal melanocytes show little phagocytic activity, when the melanocyte assumes melanomatous growth it can develop autophagic vacuoles, concentrate melanosomes in these vacuoles and consequently exhibit an increase in acid phosphatase activity⁹. It has also been shown during a study of Fortner's melanoma that this increase in lysosomal activity appears to be related to clinically observable necrosis and ulceration. As the acid phosphatase activity begins to appear in melanomatous growth the tyrosinase activity also increases, leaving a constant quantitative differential between these enzyme systems. The two enzymes are localized in different organelle systems. Thus a procedure for the simultaneous demonstration of these lytic and oxidative enzymes without abolition or cross contamination or both was developed 10 and shown to distinguish more precisely melanomatous cells as well as melanocytes from melanophages. In addition to these two lysosomal pathways in melanophages and melanomatous cells, the melanosome can follow a third route to complete its ontogeny. Another component of the epidermis, the keratinocyte, can phagocytose melanosomes from the melanocyte and ascend to the keratin layer rich in acid phosphatase where it completes its own ontogeny as well as that of its contained melanosomes (Table 1).

The lysosomal activities which we have found in the ontogeny of melanosomes have the following applications. (a) Melanophages can be clearly differentiated not only from normal junctional melanocytes but also from premalignant and malignant melanoma cells, the distinction between which is often critical, particularly after invasion

Ontogeny of melanosomes and melanocyte in the epidermaldermal structure. A junctional melanocyte actively synthesizing melano-somes shows individual occurrence of premelanosomes and melanosomes in its cytoplasm and transfers these melanosomes to neighbouring kera-tinocytes and melanophages with or without lysosomal activity. A high level dendritic Langerhans cell synthesizes its characteristic granules within its cytoplasm.

into the dermis. (b) Recent findings that the activity of lysosomes can be labilized and stabilized by various chemicals in vitro and in vivo 11 suggest a future therapeutic approach to such dermal hyperpigmentations as Riehl's melanosis and poikiloderma Civatte, for these disorders are the result of lysosomal accumulation of melanosomes. (c) It is known that malignant melanoma cells often undergo spontaneous ulceration and necrosis, and spontaneous regression has been observed12. We have found that these degradative processes are related to the ability of the melanoma cells to form lysosomes and to degrade themselves, and so the death of melanoma cells can be approached by the hormonal or chemical enhancement of lysosomal activity.

Silica in the Wall of Pediastrum

In a study of the differentiation and development of pattern and cell form in the green alga Pediastrum, difficulty in extracting pigments with organic solvents led us to examine the chemical nature of the cell wall as a preliminary to a study of wall development. Structural patterns in the cell wall of Pediastrum have been described by Moner¹, and formation of the wall by Moner and Chapman². These electron microscope studies described a network of interconnected spheres, which imparts a pattern in the continuous wall phase. Although the chemical nature of the wall was not reported, it was noted that neither the wall nor the "globular network" was noticeably affected by treatment with 17.5 per cent sodium hydroxide for 48 h, by similar treatment with ethanol-ether, or by treatment for 5 h with 70 per cent sulphuric acid. Moner had previously noted that little is known of the chemical nature of the wall. Early literature describes the wall of *Pediastrum* as two-layered³. Chodat and Huber4, on the basis of staining with chloriodide of zinc and of ammoniacal congo red, reported that there is cellulose in the inner wall layer but not the outer layer. Our attempts to identify cell wall com-

ponents by routine histochemical procedures, however, failed to give characteristic results, which suggested a possible masking of the expected wall components. We present evidence here for the presence of silica in relatively high concentration in the wall of Pediastrum. In the review on silicification by Lewin⁶, Pediastrum is not included among the algae which deposit silica, and to the best of our knowledge this occurrence has not been previously reported. It should be noted, however, that Pediastrum is recorded in the fossil record7, which indicates a very resistant cell wall.

We used cultures of Pediastrum boryanum obtained from J. S. Davis⁸ and maintained in his medium "C". Colonies heterogeneous in age were centrifuged out of suspension and subjected to oxidation in several changes of concentrated chromic and sulphuric acid for several hours at high temperatures or in concentrated nitric acid for several days. The walls of young and old colonies remained intact although the cytoplasm was removed from the cells.

Other colonies were suspended in 31 per cent perchloric acid and 34 per cent

nitric acid for 20 h to remove organic matter⁸. colonies were then washed to neutrality with water, centrifuged, and suspended in ethanol-ether (1:1) for 3 h. The extracted colonies were transferred to water and placed on grids coated with 'Formvar' for examination in the electron microscope. A young colony (Fig. 1), and an older colony which had released the inner wall and the zoospores it contained (Fig. 2), were treated in this way and revealed the retention of the characteristic wall pattern in the outer wall. To examine further the resistant nature of the wall, colonies were incinerated in a 'Pyrex' crucible under a bunsen flame. The residue was extracted for 3 days with concentrated nitric acid and washed to neutrality. Insoluble material remained, but when it was dried and exposed to hydrofluoric acid the residue dissolved. Cell walls which remained after other extraction procedures as shown in Fig. 1 also dissolved in hydrofluoric acid.

For a more positive check on the presence of silicon, indicated by solubility of the residues in hydrofluoric acid, colorimetric analysis was performed on colony suspensions after oxidation with nitric and sulphuric acids in a platinum crucible, followed by ignition and fusion with anhydrous sodium carbonate. An oxalic acid-ferrous

ammonium sulphate procedure using molybdate, which minimizes interference from iron and also from phosphate usually present as polyphosphate in certain Hydrodictyaceae10, was used to detect silicon. The blue colour characteristic of the silicon-molybdenum complex developed in the wall preparation and also in a solution of sodium metasilicate. A water control remained colour-

Silicon was also found and quantitatively estimated by the colorimetric procedure of Kilmer¹¹ in which tartaric acid reduces interference from phosphate and iron. The amount of the blue complex was determined by comparison with a standard curve established from a series of sodium metasilicate standards read at 650 mµ. The silica content of a 0.5 g sample of colonies heterogeneous in age was 0.8 per cent on an oven-dry basis.

On the basis of these analyses we conclude that the cell wall of Pediastrum boryanum is relatively high in silica. Electron micrographic studies of colonies before and after release of the inner wall containing the zoospores suggest that the silica is concentrated in the narrow outer wall of the cell. The retention of an electron-dense reticulate pattern in the wall after exhaustive extraction (Fig. 2) indicates that the pattern is also cast in silicate.

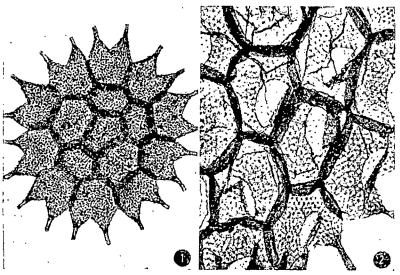

Fig. 1. Electron micrograph of young colony of *P. boryanum* after acid and ether-ethanol extraction. (×1,320.)

Fig. 2. Electron micrograph of mature colony after release of vesicle containing zoospores through semicircular pore in each cell. Colony extracted as in Fig. 1. $(\times 2,100.)$

MICROBIOLOGY

Aleutian Disease Gammopathy of Mink induced with an Ultra-filtrable Agent

Among the lymphoproliferative diseases, murine leukaemia has interested many investigators since Gross succeeded in transmitting it with a filtrable agent¹. Another lymphoproliferative disease, Aleutian disease of mink², has received considerable attention because there is a filtrable causative agent^{3,4}. Aleutian disease can be characterized as a transmissible disease of mink and possibly other mustelids⁵, in which a hypergammaglobulinaemia⁸ occurs concomitant with a plasma cell proliferation. Unlike murine leukaemia, where the ambiguity of a "filtrable agent" has been resolved by the demonstration of virus particles⁷, the Aleutian disease agent has remained undetected by electron microscopy (personal communication from R. C. Williams, jun.).

The size of the Aleutian disease agent has not been determined, and so we have carried out a series of filtration experiments. The starting material in each case was a 10 per cent spleen suspension from infected mink, prepared by blending 40 g of spleen in phosphate buffered saline, pH 7.6 (0.85 per cent sodium chloride in 0.04 molar sodium phosphate adjusted to pH 7.6 with hydrochloric acid), followed by four freeze-thaw cycles, then centrifuged at 18,000g for 30 min at 4° C. The resulting supernatant was kept frozen as a stock material. In the first experiment, part of the stock suspension was filtered through a series of 'Millipore' filters (220, 100, 50 and 10 mµ), supported on a 47 mm fritted glass grid 'Pyrex' analytical filter holder operated under vacuum at a pressure of 70 cm mercury. Previous experiments indicated that the agent of Aleutian disease could be filtered through the 100 mu filter, and so retention efficiency of the 50 m μ filter was determined with T_1 phage and the 10 m μ filter with ϕX 174 phage for E. coli by filtering the phage in an aliquot of stock tissue homogenate and then titrating turbidimetrically in a standard culture of E. coli.

A bioassay for infectivity (made in 1 yr old mink, heterozygous for the Aleutian gene) revealed filtrates derived from all of the 'Millipore' filters to be infective. The consideration that the agent for Aleutian disease is smaller than 50 m μ seemed valid, because the T_1 phage (60 m μ , ref. 8) was completely retained on the filter. The fact that the phage $\phi X174$ (25 m μ , ref. 8) was not completely retained in the conditions used for filtration reduces the significance of infectivity observed in the 10 mu filtrate. This being the case, we tried to establish the smallest size which would retain the agent for the purposes of preparation. For this, dialysis tubing was used on an LKB ultra-filter (Fig. 1). The filtration apparatus was inserted in a cylindrical flask which contained 30-35 ml. of a 10 mµ filtrate with the entire unit supported in an ice bath. Contrary to expectation, the ultra-filtrate was infective when tested undiluted (one mink/log dilution). No evidence of serum components could be demonstrated in the ultra-filtrate with rabbit antisera prepared to whole mink sera from mink infected with Aleutian disease.

As a result of this observation, ultra-filtrates were prepared directly from the stock tissue extract without previous 'Millipore' filtration. A total of three additional ultra-filtration experiments have been performed and in each instance when mink were inoculated directly with undiluted ultra-filtrates, 88 per cent of the inoculated animals developed Aleutian disease before 100 days incubation (Table 1). With the last of these ultra-filtrate preparations, radio-iodinated (iodine-125) human albumin was incorporated in the stock extract to establish the continuity of casing. For this, 'Albumatope' from Squibb and Sons, Inc., New Brunswick, was used as a marker. Before incorporation with tissue extracts, 6.4 ml. of a 1 per cent solution of 'Albumatope' was dialysed for 4 days

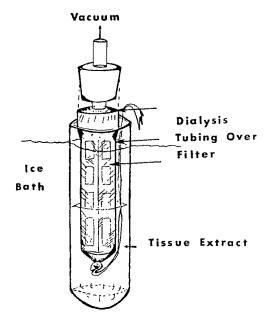

Fig. 1. Liagram showing dialysis tubing stretched over ultra-filter support. The tissue extract containing lodinated (lodine-125) albumin was placed in the cylindrical vessel.

to remove readily dissociated dialysable iodine-125. The dialysed albumin added to infective tissue extract yielded a final volume of 120 ml. (0.53 mg/ml. with 46,950 c.p.m./ml. of tissue extract). The filter was evacuated initially to 5μ pressure, then disconnected from the pump and held in an ice bath. In 4 h, 3–12 ml. of filtrate accumulated within the dialysis tubing from which it was then removed and the vacuum was reapplied. Of the total radioactivity, only 1 per cent was recovered in 35 ml. of ultra-filtrate, which indicated the system was impermeable to albumin. All estimates of radio-disintegration were made with a Nuclear Chicago model 138B scaling unit.

In instances where mink inoculated with ultra-filtrate survived for more than 30 days, pronounced hypergammaglobulinaemia developed (Fig. 2). The lesions observed in

these animals after death were identical to those seen in mink infected with tissue suspensions and 'Millipore'

There is evidence that the infective constituent of serum[®] is associated with the immunoglobulin fraction¹⁰ resulting in the complexes previously described¹¹. A

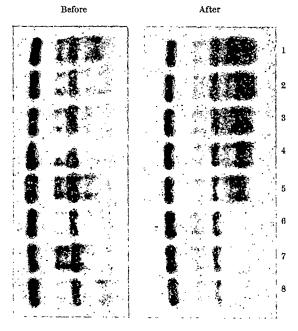

Fig. 2. Cellulose acetate electrophoresis of mink sera from animals inoculated with an ultra-filtrate. Samples 1-3 were from mink inoculated with an ultra-filtrate prepared with iodine-125 albumin marker (experiment 3) and samples 4 and 5 were from mink inoculated with an ultra-filtrate not tested with iodine-125 marker (experiment 2). Analyses were conducted on a Spinco 'Microzone' cell using the procedure recommended by the manufacturer. by the manufacturer.

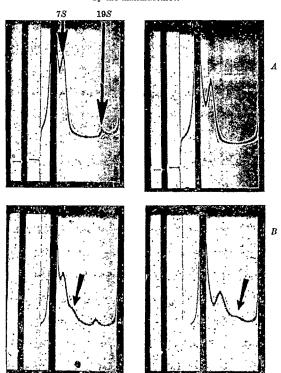

Fig. 3. Ultracentrifuge patterns (direction of sedimentation left to right) showing aggregation induced in serum diluted with an ultra-filtrate (B). A decrease in 7S components is apparent with marked increase in intermediate (arrow) and heavier components (bottom of cell). The ultra-filtrate alone produced only a salt boundary. Sedimentation was conducted at 59,780 r.p.m. at 20° C with 2-5 per cent protein.

64 min

40 min

kidney tissue ultra-filtrate prepared as already mentioned with a laboratory-constructed ultra-filter was added to hypergammaglobulinaemic serum from an infected mink (one part serum: two parts ultra-filtrate). incubation at 4° C produced aggregates which reduced the amount of material with a 7S sedimentation coefficient (Fig. 3). It is difficult to say yet whether this is a specific reaction of immunoglobulin with a renal antigen or simply the formation of strong ionic complexes with what may be the infective agent. Previous attempts to isolate the infective principle from serum by gel filtration on 'Sephadex G-200' indicated that the agent may have filtration characteristics similar to 4S components, but the possibility of ionic hold-up accounting for apparent low molecular weight components in a gel filtration pattern cannot be excluded.

The fact that infectivity of Aleutian disease was demonstrated in a fraction of tissue extract containing substances no larger than albumin makes it extremely difficult to formulate the mechanism for induction of plasmacellular proliferation in infected mink. Considering the small size of the scrapie agent 12,13 and the evidence presented here for the Aleutian disease agent, one of the few tenable explanations is that these agents are analogous to the factors responsible for induction and repression of protein synthesis and cell metabolism as described by Jacob and Monod^{14,15}. In Aleutian disease an alteration at the level of messenger synthesis, whereby a relatively small fragment might interfere with a repressor would explain the uncontrolled protein synthesis at the plasma cell level. The fact that in these animals replication of the agent takes place cannot, however, be readily explained by this theory.

Unusual Requirement for a Vitamin by Strains of Fusarium oxysporum f. sp. melonis

MANY phytopathogenic fungi do not grow in a minimal medium containing essential elements and a source of organic carbon but, in some cases, such a medium supplemented with biotin will support growth. Although nutritionally deficient mutants of Fusarium oxysporum Shlect. emend. Snyder and Hansen which require biotin have been obtained by exposing conidia to ultra-violet light2, fresh isolated strains of this phytopathogen have not been found to need biotin for growth. We now have evidence of strains which require biotin in recently isolated F. oxysporum f. sp. melonis.

Table 1. AMOUNT OF DRY MYCELIUM/100 ML. OF CULTURE MEDIUM

Strain 15a (non-deficient)	mg/100 ml.
Medium F without supplement	229
Medium $F + \text{biotin 10 } \mu g/l$.	223
Medium F + biotin 100 μ g/ml.	218
Medium F +yeast extract 1 g/l.	373
Strain 14a (deficient)	
Medium F without supplement	55
Medium F + pimelic acid 5 $\mu g/l$.	90
Medium F + desthiobiotin 5 μ g/l.	156
Medium $F + \text{biotin } 0.1 \mu \text{g/l}$.	125
Medium F + biotin 1.0 μ g/1.	185
Medium $F + \text{biotin } 10.0 \ \mu\text{g/l}$.	207
Medium F + biotin 100 0 μ g/l.	191
Medium F + yeast extract 1 g/l.	550

During a study of genetic variability in F. oxysporum f. sp. melonis, four of six isolates did not grow on the defined F medium². Using auxanographic tests, the nutritionally deficient strains grew in F medium supplemented with biotin and failed to grow when this medium contained a number of amino-acids, pyridoxine, thiamine, riboflavine, p-aminobenzoic acid or pantothenic acid.

Four Erlenmeyer flasks (500 ml.) containing F medium (100 ml.) supplemented with pimelic acid, desthiobiotin, yeast extract or graded concentrations of biotin were inoculated with about 5 x 104 conidia of one prototrophic and one auxotrophic strain. The static cultures were incubated at 26° C for 13 days and the dry mycelial weight was recorded. The average dry weights for the quadruplicated cultures are presented in Table 1.

The auxotrophic strain grew well in medium containing biotin, desthiobiotin or yeast extract, but poorly in medium supplemented with pimelic acid. All four auxotrophic strains gave the same results

The addition of extract from healthy melon plants to the F medium gave good growth for the strains deficient in biotin. The slight mycelial growth of these strains on F medium solidified with agar may have resulted from trace amounts of biotin in the agar.

Complementation tests using all possible pairs of the four auxotrophic strains were negative, which implies that the mutation leading to the need for biotin probably occurred at the same locus in these strains.

Although one nutritionally deficient strain did not lose its requirement during eight transfers at intervals of 1 month, other strains became prototrophic after being cultured for 2 yr on a yeast extract medium. Isolates requiring biotin have been obtained three times at intervals of 1 yr from the soil in the greenhouse with at least one and sometimes two crops of tomato and lettuce between crops of melon. The nutritionally deficient strains seemed to be able to compete with prototrophic strains in the greenhouse soil with a high content of organic matter. It would be interesting to determine whether other nutritionally deficient phytopathogens are favoured in such soils.

BIOCHEMISTRY

Polyacrylamide Gel Electrophoresis of Highly Purified Chick Interferon

EARLIER results1,2 suggested that chick interferon, purified by the methods of Fantes et al.1,3, was wholly or at least predominantly homogeneous, when judged by its behaviour on electrophoresis in polyacrylamide gel or in The alkaline polyacrylamide gel a sucrose gradient. electrophoresis method of Davis4 also suggested to us that the interferon was homogeneous2.

When chick interferon of even higher specific activity became available, polyacrylamide gel electrophoresis was repeated, but with slight modifications. (a) Because the overall recovery of interferon after electrophoresis was not very good and because some activity was usually found in the sample and spacer gels, these were omitted and the samples in 20 per cent sucrose were applied directly to the small-pore gel, thus raising the overall recovery. (b) There are slight variations of the rate of passage of bands in different columns, even in the same electrophoresis experiment, and so the same column (not two separate ones) was used to demonstrate the presence of both stained protein and of antiviral activity.

The technique which we used for alkaline electrophoresis was briefly as follows: interferon (in 1 ml. of 0.01 molar phosphate buffer, pH 7.5) mixed with an equal volume of 40 per cent sucrose was applied to a gel column (40×6.5 mm). The gel was prepared by polymerizing in aqueous solution acrylamide (7 per cent w/v), N,N'-methylene-bisacrylamide (0·18 per cent w/v) and N,N,N',N'-tetramethylethylene-diamine (0.056 per cent v/v), in the presence of ammonium persulphate (0.006 molar). The gel was buffered with 0.38 molar tris hydrochloric acid and the electrode buffer was as described by Davis'. After electrophoresis (6 m.amp/column) the gel was cut lengthwise, half was stained with amido black and the other was cut into twenty 2 mm pieces, each of which was placed in 1 ml. of phosphate buffer (0.5 molar, pH 7.5) containing bovine plasma albumin (500 μ g/ml.) and 'Tween 80' (20 µg/ml.). After 24 h at 4° C, the supernatant fluids were assayed for interferon content.

After alkaline electrophoresis of highly purified interferon (1.6 × 10° v/mg of protein), staining with amido black revealed two very sharp bands of protein close together; these coincided exactly with the peak of the antiviral activity (Fig. 1A). Because, however, the total activity spread well beyond the stained zones we suspected that staining and activity were not necessarily To investigate this possibility, we attempted electrophoresis at an acid pH employing essentially the method of Reisfeld et al.6, but again omitting sample and spacer gels, and applying interferon in 20 per cent sucrose to the small-pore gel, buffered with 0.38 molar sodium acetate/acetic acid. In these conditions, all or nearly all activity was invariably lost. This destruction was traced to the presence of persulphate, a substance used by both Davis and Reisfeld for catalysing their polymerizatione of acrylamide. Incubation of interferon with acid, but not with alkaline, persulphate led to complete loss of activity7,8. When gels were polymerized with riboflavine (0.0005 per cent) instead of persulphate, acid electrophoresis was successful. (We now use gels catalysed by riboflavine also for alkaline electrophoresis and the results shown in Fig. 1A were obtained in this way.)

When the same material as was used for alkaline electrophoresis was subjected to acid electrophoresis (Fig. 1B) two stained protein zones—this time well separated were again revealed, but the antiviral activity lay between them and had probably no connexion with either. The specific activity of the pre-electrophoresis sample was 1.6×10^6 U/mg of protein, and most of this protein does not seem to be part of the interferon molecule, so we assume that pure interferon will have an extremely high specific potency. Nagano et al.9-11 have suggested that the active portion of interferon is oligo- or polysaccharide. Gels, after electrophoresis of another sample of highly purified interferon (12,000 v and 8 µg of protein/ml.), were therefore stained with toluidine blue, 'Alcian blue' or carmine, dyes that reveal the presence of neutral or acidic polysaccharides. So far all results have been inconclusive. but this could be because there was too low a concentration of interferon.

The "glucose equivalent" of a sample of the same preparation of interferon was determined by means of the anthrone reagent12, and a value of 3-4 µg/ml. of

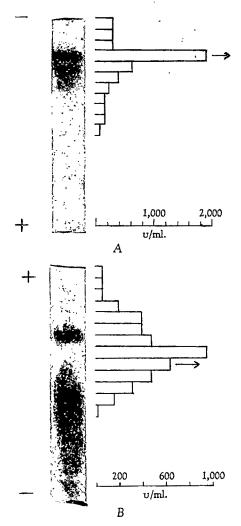

Fig. 1. Samples of 1 ml. of interferon (38,400 v/ml.; $1.6 \times 10^8 v/mg$ of protein) were subjected to alkaline and acid electrophoresis as described in the text. A, Results obtained at pH 8-9; B, those obtained at pH 3. The arrows indicate fractions the actual interferon contents of which are higher than shown, for the assay samples had not been diluted sufficiently to give endpoints.

glucose was obtained. Whether the sugar was part of interferon or of an impurity is not known.

Treatment of similar interferon samples with periodate (5 mmolar, 22° C, 5 h) at pH 7 and 4, and with trypsin (500 μ g/ml., 37° C, 2 h) at pH 7, completely destroyed activity. The result obtained with trypsin again confirmed that protein was an essential part of the interferon molecule. The results from the periodate treatment, especially that at pH 4, suggest that a sugar is also needed for antiviral activity, but this is not certain, for many amino-acids are also known to be sensitive to this re-We found that the activity of ribonuclease (100 µg/ml.), a sugar-free molecule, was completely abolished by similar treatment with periodate at pH 4, and reduced to 30 per cent at pH 7.

Chemical Inactivation in vitro of Carbonic Anhydrase by Carcinogenic Substances

The most spectacular manifestation of malign tumours is the wild proliferation of tumour cells. Besides this, there is less zinc in tissues, blood and other fluids than in healthy people¹⁻¹⁶.

In collaboration with L. J. P. Frank, we have measured the zinc content of arterial blood of 173 patients considered on clinical grounds to be suffering from various forms of carcinoma (1,900 samples were analysed by X-ray fluorescence) with the results shown in Table 1.

> Table 1 No. of patients Analytical results in agreement with diagnosis of physician 173 (100%) 144 (~83%) 2 (~1%) 27 (-16%) Uncertainty Conflicting opinions

We have found repeatedly that the concentration of zinc in the blood parallels the progress of the illness and that for diagnostic purposes it is useful to monitor the zinc concentration of the blood of its components14.

The concentration of zinc has previously^{3,7,8,18,17} been related to that of metallo-protein carbonic anhydrase, an enzyme which regulates the transport of carbon dioxide. This regulation depends on a catalytic process, which takes place between carbon dioxide and water adsorbed (chemisorption) by chelate-bound zinc25.

Human carbonic anhydrase (HCA) can be split by paper electrophoresis into three principal fractions (Fig. 1): a small fraction of the isoenzyme A with low activity; a large fraction of the isoenzyme B, also with low activity (this fraction contains "loosely bound" zinc, which can easily be removed by extraction with dithizone at pH 6.8); and a smaller fraction of the isoenzyme C with very high activity23,24. (For the three-dimensional structure of $HCA-\tilde{C}$ see ref. 26.) The third fraction contains "firmly bound" zinc, which can be removed by extraction with

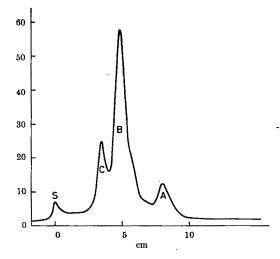

Fig. 1. Filter paper electrophoretic pattern of human carbonic an-hydrase (veronal buffer pH 8-6, for details see text). Abscissa: distance from site of application (S) of sample; ordinate: measured absorption of light on arbitrary scale.

o-phenanthroline (a compound with a strong affinity for zine), but not by extraction with dithizone at pH 6.8.

It is possible¹⁷ to remove firmly bound zinc by irradiation with soft X-rays (irradiation specifically into the zinc absorption band loosens the bond between the zinc and the organic molecule), and as this removal proceeds, the activity of the carbonic anhydrase becomes reduced17,18 in proportion. Thus it seems that the amount of "firmly bound" zinc determines the activity of carbonic anhydrase.

The purpose of the present investigation was to see whether it is possible to loosen the firmly bound zinc from carbonic anhydrase by contact with carcinogenic agents. As far as carcinogenic derivatives of anthracene are concerned, they are characteristic in their binding of osmium tetroxide and in possessing the "K-region" in the molecule which is strongly unsaturated. This unsaturated part of the molecule might be able, like the X-rays, to disrupt the chelate bond by which the zinc is held in the enzyme. It might then be possible for covalent linkages to be formed, as between DNA and butter yellow22.

Carbonic anhydrase is only soluble in water, anthracene derivatives form stable suspensions in organic solvents like olive oil, and so carbonic anhydrase and anthracene derivatives can only be brought together at the oil-water interface. At the interface the enzyme will react in the denatured form.

A preliminary experiment showed that shaking together a solution of carbonic anhydrase (1 mg in 5 ml. of water) and a suspension of 1 mg of anthracene derivative in 150 mg of olive oil produced an almost stable emulsion. If this emulsion was kept at 37° C, shaking once a day was sufficient.

We found that a reaction time of 5-10 weeks was sufficient to produce a significant effect. Table 2 shows the results after 10 weeks. (All handling was performed in sterile conditions. Neither sedimentation nor a smell of hydrogen sulphide could be observed after 5 weeks storage at 37° C, and there was no development of bacteria.) Sometimes, however, a creamy discoloration was seen, and the results of these experiments were unreliable.

Two kinds of known carcinogen were chosen: 1,2-benzanthracene, a weak carcinogen: and 1,2,5,6-dibenzanthracene, a potent one¹⁸. The carbonic anhydrase was a bovine preparation from Koch-Light Laboratories. It contained 0.10 per cent loosely bound zinc; after destruction with oxidizing acids we found 0.17 per cent total zinc; this batch therefore contained 0.07 per cent firmly bound zinc.

Table 2. Change in the concentration of firmly bound zinc in carbonic anhydrase after storage for 10 weeks at 37° c with carcinogens

	Loosely bound	Total	Firmly bound
Original solution Storage with suspension of pure oil The same, but 1,2-benzanthracene added The same but 1.2.5.6-dibenzanthracene	0·10% 0·09*% 0·10%	0·17% 0·16*% 0·16%	0·07% 0·07% 0·06%
The same but 1,2,5,6-dibenzanthracene added	0.12%	0.16%	0.045%

The decrease in firmly bound zinc, shown in the last column of Table 2, was statistically significant. The stronger the activity of the carcinogenic agent, the less firmly bound the zinc remains, which can lead to lower activity of the carbonic anhydrase17,18.

Next we established that after storage for 18 and 34 weeks, respectively, there was no further change. The deionized water which we used may have contained some organic substances; in the next experiment, therefore, we used distilled deionized water, for it was possible that organic substances have an inhibitory effect. The results are shown in Table 3, where we have also included results obtained with anthracene, which is not carcino-

Eleven weeks later there had been almost no further change. All measurements were made at least in triplicate; the differences in the triplicate measurements were negligible (± 0.005 per cent). Full details of the chemical analysis will be described elsewhere. The determination of zinc with dithizone reference has already been discussed²¹. The preparations of HCA were made up chiefly according to Keilin and Mann²⁰. (Electrophoresis at pH 8.6 (veronal sodium/veronal buffer); voltage 150 V was carried out for 23 h.) The electrophoretic work was performed in the biochemical department of this labor-

Table 3

	bound zine	zinc	bound zinc
Storage, only oil added The same, but anthracene added The same, but 1,2-benzanthracene added The same, but 1,2,5,6-dibenzanthracen	0·11 ⁴ % 0·11 ⁴ % 0·13%	0·18*% 0·18*% 0·18%	0·07% 0·07% 0·05%
added	0.15*%	0.18%	0.025%

As for Table 2, but with distilled deionized water after storage for 5 weeks at 37° C.

To sum up, it can be said that an important side effect in cases of carcinoma is the decrease in the content of zinc (compared with that in healthy people) in tissues, blood and so on. This element occurs with two different types of bonding in the metallo-protein carbonic anhydrase, an enzyme controlling the transport of carbon dioxide. The difference between firmly bound and loosely bound can be determined with dithizone. The amount of firmly bound zinc can be related to fraction C (Fig. 1) into which carbonic anhydrase can be separated, in addition to the fractions B and A, by paper electrophoresis.

The amount of firmly bound zine is the principal correlative of the activity of the enzyme. This amount can be reduced either by irradiation with X-rays of a frequency corresponding to the zine absorption band or in vitro by chemical reaction with carcinogenic agents. The greater the carcinogenic effect of these substances, the more of the firmly bound zinc is loosened and the smaller the activity of the enzyme.

We thank Drs A. D. F. Addink, H. J. van den Berg and W. Hoogenstraten for their advice.

Effect of Valinomycin on Net Sodium and Potassium Transport in Ehrlich Ascites Tumour Cells

Gordon et al.¹ speculated that in the mitochondria of intact tumour cells there is a mechanism dependent on valinomycin for the uptake of potassium directly from the cell environment. This mechanism is thought to act independently of the plasma membrane potassium ion transport system. It is well known that in the presence of valinomycin isolated mitochondria accumulate large amounts of potassium ions². Thus the demonstration of potassium ion uptake which is independent of the plasma membrane localized mechanism in the intact cell would be very interesting.

To test the hypothesis that valinomycin could stimulate the mitochondria of intact cells to accumulate potassium ions from the cell environment, cellular respiration, net flux of sodium and potassium ions, and ATP content were measured with the plasma membrane transport system operative or inhibited. The results reported here show that in cells depleted of potassium ions, valinomycin was incapable of stimulating their uptake or the extrusion of sodium ions. Rather, in the presence of this antibiotic, the cellular ATP decreased rapidly with a concomitant loss of potassium ions and gain of sodium ions. The data therefore indicate that only the transport system of the plasma membrane is able to move external potassium ions into the intact cell.

Experiments were performed with Ehrlich-Lettré ascites tumour cells that were maintained in HA/ICR Swiss mice by weekly transplantation. Methods for the preparation of cell suspensions have been described previously³. In some experiments, cell suspensions $(2-3 \times 10^7)$ cells/ml.) were maintained in potassium-sodium Ringer solution³ under 100 per cent oxygen, to maintain normal sodium and potassium ion content. In other experiments, cell suspensions were maintained at 4° C in potassium ion free Ringer solution for 5 h to permit the loss of potassium ions and gain of sodium ions. For net flux experiments, cells incubated at 4° C were washed once with cold potassium-sodium Ringer solution, and then quickly warmed to 25° C. Samples of 1 ml. (2-3×107 cells/ml.) were removed sequentially and the cells were washed quickly in cold isosmotic choline chloride. Sodium and potassium ions in the cell were measured by flame photometry, and ATP was measured fluorometrically4. Oxygen consumption was measured with a Clark oxygen electrode and a chart recorder. (107 cells corresponded to 24 mg wet weight, 4.7 mg dry weight and 3.3 mg protein.)

The effect of valinomycin on oxygen consumption is shown in Table 1. The addition of valinomycin to cells with a normal content of potassium and sodium ions,

Table 1. INFLUENCE OF VALINOMYOIN ON THE RESPIRATION OF NORMAL CELLS AND CELLS DEPLETED OF POTASSIUM IONS

Normal cells: Control rate	oxygen consumption Additions	(μmoles/10 [†] cells/h) Rate
1·07 1·01	Val. KCl	1.62 0.990
1.10	Then Val. Oligo. Then Val.	1.58 0.297 1.05
Depleted cells: Control rate	oxygen consumption Additions	(μmoles/10 ⁷ cells/h) Rate
0-490	Val.	0.520
0.450	Then KCl KCl	1·20 0·890
0.475	Then Val. KCl	1·10 0·890
(Ouabain present)	Then Oligo. Then Val.	0·210 0·900
0·500	KCl Then Val.	0·550 0·880

Normal medium was potassium-sodium Ringer solution; that of depleted cells was Ringer without potassium ions. Potassium was added to a final concentration of 5 mmolar. Valinomycin was added to $3\times10^{-3}~\mu g/10^{7}$ cells, oligomycin to $0.8~\mu g/10^{7}$ cells, ouabain to 5×10^{-4} molar. A volume of 1 mi. of cell suspension (5×10^{7} cells) was added to 4 ml. of medium. The temperature was 25° C.

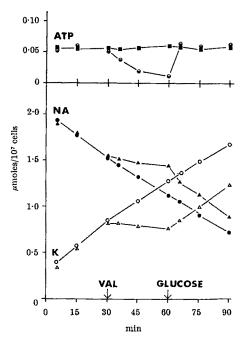

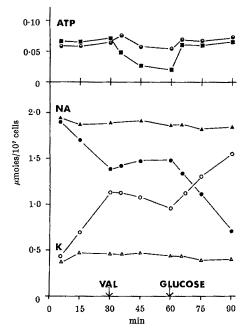

Fig. 1. Effect of valinomycin on net transport of sodium and potassium ions and on ATP content. Two flasks of cells depleted of potassium ions (2·5 × 10⁷/ml.) in potassium-sodium Ringer solution were warmed from 4° to 25° C at zero time. At the time indicated valinomycin (3 × 10⁻³ μ g/10⁷ cells) was added to the experimental flask, and glucose (final concentration 6 mmolar) was added to both flasks. Control: (K) — O — O, (Na) — • (ATP) — Experimental: (K) — \triangle — \triangle , (Na) — • (ATP) — • (ATP) — • (Na) — • (Na) — • (ATP) —

which oxidized endogenous substrate, was a prompt stimulation of respiration. Furthermore, valinomycin when added to oligomycin-inhibited cells caused an immediate release of inhibition. Addition of valinomycin to cells containing few potassium ions and many sodium ions (temperature changed from 4° to 25° C) also resulted in a stimulation of respiration and a release of oligomycin inhibition. In addition, the inhibition of respiration by ouabain was relieved by valinomycin. The effect of valinomycin on respiration and its dependence on external potassium ions confirm earlier observations¹.

In the presence of valinomycin isolated mitochondria can accumulate many potassium ions from the environment, and so experiments were carried out to determine whether valinomycin could stimulate the accumulation of potassium ions in intact depleted cells of these ions.

Fig. 1 shows that when cells depleted of potassium ions were warmed from 4° to 25° C, they accumulated these ions and extruded sodium ions. When, however, valinomycin was added the cellular ATP content declined and the net cation transport was inhibited. Addition of glucose to this system restored cellular ATP (by glycolysis) to the control value which then supplied energy for the accumulation of potassium ions and extrusion of This finding is consistent with other work sodium ions. which showed ATP to be essential for cation transport in these cells. Fig. 2 shows the inhibitory effect of ouabain on net sodium and potassium ion transport, and the inability of valinomycin to relieve the inhibition. Ouabain alone had no effect on the ATP content, but when valinomycin was added there was a significant decrease. Glucose restored ATP to the control value, but this did not result in the accumulation of potassium ions or the extrusion of sodium ions. It follows that even in the presence of adequate ATP valinomycin was unable to induce mitochondrial uptake of potassium ions from the medium or extrusion of sodium ions from the cells.

We suspected that oligomycin specifically inhibited the plasma membrane cation transport system (similar to ouabain), and so we have investigated its effect on net transport and ATP content. The data in Fig. 3 demonstrate that potassium uptake and extrusion of sodium were inhibited because of reduced ATP content. The addition of valinomycin, sufficient to relieve respiratory inhibition, resulted in further loss of potassium ions and gain of sodium ions, but had little effect on the residual ATP content. The addition of glucose to this system restored the ATP content and initiated

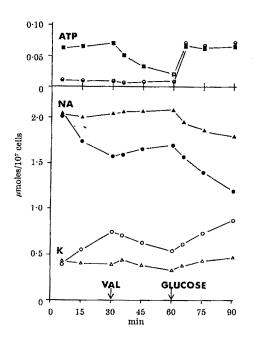

Fig. 3. Effect of valinomycin in the presence of oligomycin on net transport of potassium and sodium ions and ATP content. See Fig. 2 for a description of the experimental procedure and an explanation of the symbols. Oligomycin $(0.8~\mu g/10^7~{\rm cell}_3)$ was added to the experimental flasks.

the extrusion of sodium ions and the accumulation of potassium ions. This suggests that oligomycin does not act exclusively at the level of the plasma membrane, but rather this antibiotic acts at a mitochondrial site to inhibit ATP synthesis.

The results reported here are consistent with the suggestion that valinomycin stimulates the activity of mitochondrial ATPase2, which results in increased respiration. This enhanced activity is thought to utilize rapidly the available ATP and thus inhibit the plasma membrane cation transport system. The restoration of net fluxes after the addition of glucose indicates that valinomycin did not directly interfere with the transport mechanism, but that this antibiotic caused a rapid dissipation of cellular energy reserves. Ouabain, however, specifically inhibited net transport of sodium and potassium ions. Valinomycin was unable to overcome this inhibition even when adequate cellular ATP was present, and so we conclude that there is no path for the uptake of potassium ions from the medium directly to the mitochondria and independent of the plasma membrane transport system in the ascites tumour cell.

This work was supported in part by a grant from the American Cancer Society.

Gel Permeation Chromatography: Gel Preparation and Packing Technique

Since the original publication by Moore¹, gel permeation chromatography has been widely recognized as a rapid means of assessing the molecular weight distributions of polymeric materials soluble in organic solvents. While the use of this technique, principally based on the reliable commercial instrument², is well established, reference in published work to the preparation of the cross-linked polystyrene gel, and its packing into columns with high plate count, is very brief. Some information is to be found in the writings of Moore¹ and Altgelt³ and in the review of Johnson, Porter and Cantow⁴. This communication describes how gels of varying porosity may be prepared, and packed into columns having a plate count within the range 700–1,300 theoretical plates/ft.

The gels were prepared using a suspension polymerization of a mixture of styrene, divinyl benzene and diluents. Trial experiments quickly showed that a workable pressure drop of less than 40 p.s.i. across a 4 ft. column was achieved with gel particles lying within the range 15 to 90µ. A partially hydrolysed polyvinyl acetate ('Gelvatol' 30-60) was used as a suspension stabilizer, as suggested by Winslow and Matreyek⁵. A typical preparation was as follows: a solution of 20 g of 'Gelvatol' in 1,200 c.c. of water was placed in a 2 l. flask fitted with a collapsible paddle measuring 2.5 in. by 0.5 in. The flask was heated to 70° C and a mixture of styrene, divinyl benzene (55 per cent divinyl benzene plus 45 per cent ethyl vinyl benzene) and diluents, having a total volume of about 300 c.c., were added. The monomers had been previously freed from stabilizer by washing in alkali, and 1 g of benzoyl peroxide was used as initiator. Polymerization was allowed to proceed at 80° C for 7 h using a stirring

rate of about 500 r.p.m. After cooling and decanting, the gel particles were washed with hot water and acetone in order to remove stabilizer and organic materials.

In spite of the experimental conditions the particles were found to be agglomerates and these were broken down by ball milling for 3 h in a polyethylene bottle containing 0.25 in. porcelain balls. The milled particles were suspended in acetone and the suspension sieved through a 63 or 90 μ sieve. The suspension passing through the sieve was degassed by boiling and cooling in a stoppered vessel. The fine particles (less than 15 μ) were removed by sedimentation in acetone. A 2 l. beaker, filled to a depth of about 5 in., was used to disperse the gel, and after standing for about 30 min, the finer particles were decanted away. This separation process was repeated three times.

Microscopic examination of these particles showed them to be irregular in shape, not spherical as neight be expected. Because they could be packed into columns having high plate counts, however, the lack of clearly defined shape appears to be of no consequence.

The columns were constructed from lengths (4 ft.) of stainless steel tubing with a $\frac{3}{4}$ in. external diameter and 20 s.w.g. walls. End-fittings of the type illustrated in Fig. 2 were fashioned from modified Wade couplings, which incorporate a 'Porosint' sintered bronze disk of $\frac{3}{4}$ in. diameter and 1/16 in. thickness, of grade D, with a maximum pore size of 25μ . A brass plug A, through which passes a stainless steel hypodermic tube (1/16 in. external diameter), rests on top of the sinter B. The plug A has both radial and concentric grooves in an attempt to maintain plug flow, and is slightly dished with respect to the sinter. The connecting tubing is brazed into part C, which on tightening presses A into intimate contact with B, and seals on the shoulder D. All parts are a good tight fit.

The pressure packing apparatus is shown in Fig. 3, where all the necessary details are given. It is based on the design first given by Waters². The micropump (D.C.L. type M) is capable of delivering zero to 3,100 c.c. per hour. The apparatus may be clipped to a rigid back board during use.

A typical packing procedure was first to degas 2 l. of tetrahydrofuran (THF) by boiling and cooling, 0·1 per cent of 2:6-ditertiarybutyl-p-cresol being added as

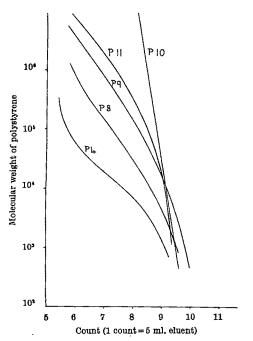

Fig. 1. The permeability curves for the gels prepared as described.

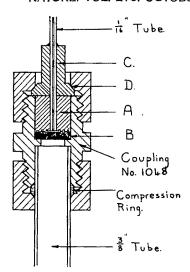

Fig. 2. Details of the end-fittings designed for the chromatographic columns.

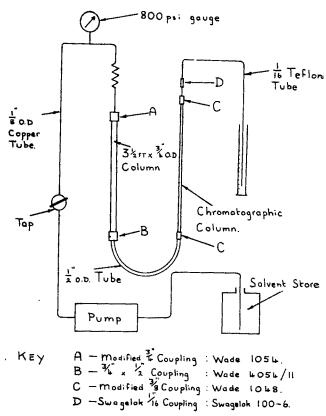

Fig. 3. Details of the column packing assembly used for the packing of the chromatographic columns with crosslinked polystyrene gels.

stabilizer, and placed in the solvent store. About 100 c.c. of dry gel was placed in a balanced solvent mix (a mixture of acetone and perchloroethylene in approximate ratio 6:5 by volume). The resultant slurry was degassed by boiling and cooling, a small sample centrifuged, and thus the solvent mix was accurately balanced against the density of the gel. This accurately balanced mix was then added to the supply tube, and the remaining space filled with balanced mix. The pump was started so as to deliver 1 c.c. per minute, and when the THF emerging from the supply line was free from air, the connexion was made to the supply tube. Pumping was maintained at 1 c.c./min until about 10 c.c. had been collected, and then the pumping rate increased until the gauge indicated

550 p.s.i. During the subsequent packing operation the pump stroke was decreased in order to maintain the recorded pressure at the same level. After passing 400 c.c. of solvent pumping was stopped and a 10 c.c. hypodermic syringe, filled with THF, attached to the 'Teflon' tubing at the exit. This syringe was held at a higher level than the column, and the supply tube was disconnected from the U-tube. The column and U-tube were then inverted, and the U-tube removed. A little gel was taken from the U-tube and placed on the porous disk of the end-fitting finally used to close the column. The hypodermic syringe was then depressed to pass THF through the end-fitting before finally sealing the column with bellows containing THF.

Table 1. Permeability of Gels prepared using 6.7 per cent styrene, 33.3 per cent divinyl benzene, and 60 per cent diluent

Gel	P4	P 8	P9	P10	P11
Per cent styrene	6.7	6.7	6-7	6.7	6-7
Per cent divinyl benzene	33-3	33.3	33-3	33.3	33.3
Per cent toluene	15				
Per cent n-dodecane	45		_	*****	_
Per cent diethyl benzene		16	10	5	7.3
Per cent isoamyl alcohol		44	50	55	52-7*
Porosity limit A	2×10^{3}	3×10^{4}	2×10^{5}	1012	5 × 10 ⁶

All percentages relate to composition by volume.

* A mixture of 78 per cent 3-methyl butanol and 22 per cent 2-methyl * A mi butanol.

The permeability curves for these gels packed into a 4 ft. column are given in Fig. 1.

The estimated porosity of the gels prepared as described here is given in Table I. The plate counts, determined by injecting 1 per cent trichlorobenzene in THF, for 15 sec at a flow rate of 1 c.c./min, with the refractometer at normal sensitivity, fell within the range 700-1,300 theoretical plates/ft.

Variations dependent on Age and Diet in the Metabolism of 7,12-Dimethylbenz[a]-anthracene by Rat Liver Homogenates

7,12-DIMETHYLBENZ[A]ANTHRACENE (DMBA) severe adrenocortical necrosis when administered intragastrically to 50 day old rats1, but it has no effect on the adrenal glands of 25 day old animals2. The activity of the hydrocarbon seems to depend on the formation of an active metabolite, probably 7-hydroxymethyl-12-methylbenz[a]anthracene (7-OHM-12-MBA)^{3,4}; the isomeric 12hydroxymethyl-7-methylbenz[a]anthracene (12-OHM-7-MBA) is a metabolic product of DMBA but has no effect on the adrenal³. Damage to the adrenal can be prevented by pretreating animals with compounds that enhance hepatic detoxicating enzymes^{5,8}, apparently by increasing the yields of inactive ring-hydroxylated products, such as 8,9-dihydro-8,9-dihydroxy-7,12-dimethylbenz[a]anthracene, at the expense of those hydroxylated on the methyl groups and also by inactivating 7-OHM-12-MBA itself by ring hydroxylation, to yield products such as 8,9-dihydro-8,9-dihydroxy-7-hydroxymethyl-12-methylbenz[a]anthra-Treatments which reduce hepatic detoxicating enzymes also prevent DMBA-induced adrenal necrosis8, probably by reducing the overall metabolism of the hydrocarbon. It seemed possible that the differing susceptibilities to DMBA-induced adrenal necrosis of the 25 and 50 day old rats developed because animals of the two age groups have different activities of hepatic enzymes, and so we have investigated the in vitro metabolism of DMBA by liver homogenates prepared from rats of different ages.

Livers from at least two rats of the same age and sex were pooled and homogenates prepared by methods previously described. DMBA (generally labelled with tritium, specific activity 400 mc./mmole) was added in ethanol (3.8 × 106 c.p.m. in 0.1 ml.) to duplicate portions of homogenate (each equivalent to 1 g of liver) and the mixture was incubated at 37° C for 30 min. Unchanged hydrocarbon and the metabolites formed were extracted with ethyl acetate and separated by thin-layer chromatography on plates coated with silica gel G and developed for 15 min in benzene-ethanol (9:1, v/v)7. The 8,9-dihydro-8,9-dihydroxy derivative of DMBA showed as a violet fluorescent band of R_F 0.30 when examined in ultra-violet light. The 8,9-dihydro-8,9-dihydroxy derivatives of 7-OHM-12-MBA and 12-OHM-7-MBA could not be detected by this means. These derivatives had R_F 0.21 in the solvent system used, and a band in this region of the chromatogram and also the band at R_F 0.30 were removed. The radioactivity of the silica gel was measured by liquid scintillation counting.

The results show that the ability of rats to metabolize DMBA, as measured by the formation of 8,9-dihydro-8,9-dihydroxy-7,12-dimethylbenz[a]anthracene (Fig. and to metabolize the 7-OHM-12-MBA and 12-OHM-7-MBA, as measured by the formation of the corresponding 8,9-dihydro-8,9-dihydroxy compounds (Fig. 2), increases sharply in rats between 15 and 25 days old and then falls to a basal value in adults. Compounds known to increase DMBA and 7-OHM-12-MBA metabolism⁷ also protect against the adrenocorticolytic effect of the hydrocarbon10,11, probably by reducing the effective concentration of 7-OHM-12-MBA, and it seems likely that the absence of adrenal damage in 25 day old rats treated with DMBA is the result of an increase in DMBA metabolism to yield

ring-hydroxylated products.

No increase in the ability of rats to metabolize DMBA as compared with control animals was found when liver homogenates were prepared from litters of 25 day old unweaned rats whose only source of food was their mothers' milk from 15 days old (Table 1). Similar results were obtained from litters of 25 day old rats that had been fed sweetened condensed milk from 15 days old. When, however, liver homogenates from unweaned or milk-fed 25 day old rats, subsequently transferred to a diet of rat cubes (Diet 86, Plowco Feeds, Ltd.) for 10 days, were used, DMBA metabolism increased (Table 1).

^{*}Age of rats when liver homogenates were prepared.

In adult animals, both DMBA and 7-OHM-12-MBA are metabolized by hepatic microsomal hydroxylating systems that are enhanced by pretreatment with some foreign compounds7. One interpretation of these results is that the increase in the metabolism of DMBA by liver from 25 day old rats is caused by an induction of microsomal enzymes by dietary components first ingested during weaning. The fact that this increase in DMBA metabolism can be delayed in rats restricted to milk diets supports this view. Further support is provided by the results of recent studies of hexobarbital metabolism in mice where variations with age have been examined12. Hexobarbital sleeping time was minimal in 21 day old animals and this was found to coincide with maximum liver metabolism: in some earlier work with this drug these effects were not noted13. There is some evidence that, in rats, the toxicity of DMBA increases between 25 and 50 days1: this also supports the concept of enhanced microsomal enzyme activity in weanling animals.

The apparently transient nature of the increase in DMBA hydroxylating activity of rat liver at weaning is also of interest in view of the report that the chronic administration of DDT to rats causes only a temporary increase in the aniline hydroxylating capacity of the liver: in these same animals DDT caused a continuous increase in the liver enzymes metabolizing hexobarbital, aminopyrine and p-nitrobenzoic acid14.

The increases in the hepatic metabolism of DMBA in rats and of hexobarbital in mice found to coincide with weaning indicate that the possibility of diet-dependent variations in microsomal enzyme systems should not be overlooked, particularly where experiments cover the normal weaning period for the species used.

We thank Professor E. Boyland for his interest and Miss J. Brangwin and Mr A. Hewer for technical assist-

Multiple Analyses on a Single Gel **Electrophoresis Preparation**

GEL electrophoresis has been shown to be a rapid means of producing high resolution separations of proteins1,2, although some of the resolved components may be artefacts when the so-called disc technique is used3. It is difficult to correlate the results of replicate disc separations because of variations from one gel cylinder to another4, but by applying multiple samples to a single acrylamide gel slab⁵, using the vertical acrylamide gel slab technique originally described by Raymond⁶, individual components of many samples processed together on the same gel slab can be traced across sample boundaries with high reliability, using the principle of continuity8.

The equipment used is the vertical gel electrophoresis cell of Raymond⁶ which provides a gel slab 125 × 175 mm between two parallel water-cooled plates 6 mm apart (Fig. 1). Direct water-cooling of the gel significantly improves the reproducibility from run to run, and makes possible the use of low temperatures (for example, for use with thermally sensitive proteins) or high temperatures (for example, when it is desirable to keep 12 molar urea in solution). The design of the cell makes it unnecessary to rely on gaskets or dialysis membranes to retain the gel during polymerization. The cell is easily dismantled to remove the gel slab at the end of the electrophoresis run. When both running and spacer gels are to be used1,2, the bottom of the column is occluded by polymerizing a plug of running gel in place, with the cell supported at an angle of 45°. The column is then placed

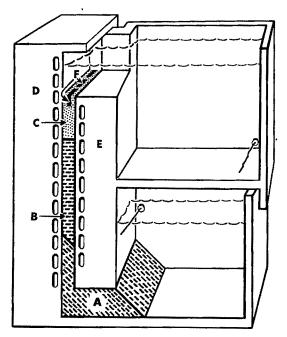

Fig. 1. Vertical gel electrophoresis cell, cross-section showing position of gel slab. A, Gel plug; B, running gel; C, spacer gel; D, outer cooling plate; E, inner cooling plate; F, sample slots.

vertically and filled with running gel solution to the desired level. Water is overlaid to ensure a planar interface between running gel and spacer gel. After polymerization of the running gel, the column is rinsed out and filled with spacer gel solution, which is polymerized in the horizontal position, using a slot-form as described. After polymerization, the gel column is placed vertically, the excess gel and slot form removed, and the electrode chambers filled with buffer. At this point, catalyst residues can be removed from the gel, if necessary, by pre-running with no samples in place. The column is now ready to receive the samples into the sample slots. The use of slots permits up to sixteen samples to be run in parallel under identical conditions without intermixing, and prevents edge effects from affecting the uniformity of the patterns.

Several points deserve particular mention.

- (a) The sample is applied in solution, avoiding the artefacts and loss of sample components which occur when the sample is polymerized into a sample gel. The density of the sample solution must be greater than that of the electrode buffer.
- (b) In order to maintain a straight buffer front, the sample slots must be filled to the top of the gel with a solution of approximately the same buffer composition and pH, and with nearly the same viscosity effect, as the spacer gel. These requirements, and also the density requirement, are conveniently realized by diluting the sample solutions with polymerized acrylamide solution (omitting cross-linking agent) dialysed against the appropriate buffer until free of catalyst residues. A sample is diluted with this buffered acrylamide solution so that a volume sufficient to fill the sample slot contains the appropriate amount of protein. The subsequent electrophoretic separation is performed by the use of standard techniques.
- (c) In order to preserve direct intercomparability of pattern, especially when individual components are to be identified in several different samples using the principle of continuity, staining techniques must be used which do not require cutting the gel slab apart.
- (d) For application of different stains, it is usually possible to immerse selected portions of the slab in separate staining solutions without cutting it apart.

Alternatively, an agar layer containing the appropriate reagents can be applied to selected portions of the slab. In many systems it is possible to apply different staining solutions in sequence to the entire slab. Fig. 2A shows the appearance of one such slab successively stained with

Observations on the Metabolism of Fluoride in Acacia georginae and Some Other Plants

When working with homogenates of Acacia georginae in an attempt to trace the pathway of fluoroacetate synthesis, we found that there was a loss of fluoride, and we extended our experiments to some other plants to study this effect. This communication describes experiments which have led us to believe that plants can convert fluoride, possibly in part, to a volatile form.

A plant of Acacia georginae, 15 months old and about 9 in. high, grown from seed, was used. A homogenate was made from 4.6 g of mixed leaves and small roots in the mortar as previously described. The homogenate and washings were reinforced with specially prepared sodium pyruvate (1.0 mmole), manganese chloride (0.1 mmole), potassium dihydrogen phosphate (0.01 mmole brought to pH 7.0 with sodium hydroxide), and ATP (0.1 mmole) to make a total volume of 10.8 ml. Three millilitres was kept as a control, and sufficient fluoride was added to the remainder to make a concentration of 40·0 μg/g of plant. The latter sample was then incubated at 30° C with a slow passage of 95 per cent oxygen with 5 per cent carbon dioxide over it for 2 h, after which the two samples were deep frozen. After standing overnight, the homogenates were allowed to thaw and centrifuged at about 50,000g for 20 min. The separating solid was washed once with water. Determinations of fluoride were made on both the control and the sample with added fluoride: estimations of inorganic F- by diffusion and total F- by diffusion after combustion in the supernatants were made by the technique of Hall² and the total fluoride in the "solid" was also determined. The results are given in Table 1.

Table 1. METABOLISM OF FLUORIDE BY A REINFORCED HOMOGENATE OF A. georginae

Fluoride ($\mu g/g$ wet weight)						
Fluoride added	Inorg. F-	Total F	Solid F-			
Nil	2.4	2.3	2.3			
40.0	24.0	24.0	7.2			
Loss of fluoride adde	d-33.8 per cen	ıt.				

Making allowance for the fluoride originally present, the fluoride recovered in the total F-+solid was 26.5 µg/g, making a loss of fluoride of 33.8 per cent. It is to be noted that this older plant showed no synthesis of organically combined fluoride. Similar and even greater losses of fluoride have been observed in other experiments with homogenates of the Australian plant.

The phenomenon observed with A. georginae led to a similar trial with homogenates of other plants taken at random. The results are given in Table 2 and are calculated in the same way as Table 1. Losses of fluoride varied from 15 to 52 per cent.

There seems to be no doubt that the phenomenon is not confined to the Acacia, and may be rather general. An attempt to identify the volatile constituent is in progress.

We realize that our conclusions depend entirely on the accuracy of our methods, so we have spent much time in deciding that these losses are not due to experimental error. Errors caused by the fluoride combining with glass were eliminated by using 'Pyrex'. We proved that silicates and various metals combusted with F- did not interfere and also that our colorimetric stage in Hall's technique² was insensitive to acetaldehyde (1.0 mg) and formaldehyde (0·1 mg).

Our final figures are a summation of four separate estimations—that for total fluoride, and for fluoride in the separated solids, except in Asclepias, where no solid separated (see footnote to Table 2). Each figure is the average of satisfactory duplicates. Even if we assume that there is an underestimation of 1.0 per cent for the homogenate plus added fluoride and a similar overestimation for the residual fluoride in the control, this would only add up to a total of 8 per cent. Allowing a figure of 5 per cent for possible losses by adsorption on the glass, errors of 15 per cent could be reached by supposing that the errors are all additive. Even so, an experimental error of 15 per cent still leaves a substantial loss in many experiments. We have not yet related the losses to different stages of growth, so the difference between the two experiments on Asclepias, taken at different times, is not significant.

We can find no reference in the literature to the conversion of added fluoride to a volatile form by plants, and conclude that the observations are new. We have made some attempt to prove volatility of fluoride by using the radioactive isotope fluoride-18, supplied by the MRC Cyclotron Unit. The short life of this element of about 110 min precludes investigations for longer than 6-7 h. There is also the handicap that we do not yet know the nature of the volatile fluorine compound. Nevertheless, we have passed the mixture of oxygen and carbon dioxide from our homogenates of both A. georginae and Asclepias successively through water, ethanol and mercury per-chlorate, and at the end of 1 and 1.5 h, respectively, a significant amount of radioactivity has been detected in these solutions. The amount is small, but we know from other experiments that, for example, the absorption of methyl fluoride is very inefficient, so that the experiments again show the presence of volatile fluoride.

Our experiments have been made on homogenates in vitro, so that it has still to be proved that any effect occurs in vivo, or that the losses are all explained by volatility. It is natural to associate the loss of F- with the formation of ethylene which has been proved to be formed in our homogenates³. The aim in our research on the Acacia plant has been to find the biochemical path for the synthesis of fluoroacetate. We think it possible that

Table 2. LOSSES OF FLUORIDE FROM HOMOGENATES OF VARIOUS PLANTS

Plant	Part taken	Weight (g)	Volume (ml.)	F- added (µg/g) wet weight	Per cent fluoride disap- pearing
Asclepias curassavica	Leaves	3.1	7.0	55.3	31.0
(6 months)	Leaves	2.9	5.3	26.2	52.5
Pea: 'Laxton Superb	,	-			
(1 month)	Seedlings	16.0	12.0	90-5	28.0
Early 'Gradus'	Seeds	12.6	9.0	11-65	26.0
Poa annua	Whole seedling	11.0	8.0	10.42	43.5
•	Seedling	5.64	8.0	33.6	14.5
Felicia pappei	Whole	7.0	8.5	15.9	41.5
variety Gracilie	Not in flower	25.8	25.0	40.5	36-0
Aquilegia canadensis	Whole	$2 \cdot 2$	5.0	31.8	46.0
(8 weeks)	Whole	3.35	8.0	40.0	15.0
Acacia armata	Leaves and				
	fine roots	3.0	6.2	20.2	33.0
Thea chinensis	New leaves and				
	fine roots	4.3	8.0	35-4	35.0
Doronicum	Flowers	7.6	11.0	35.1	39.5

In the case of Asclepias, it was possible to sample the treated homogenate without centrifuging and so to eliminate the extra error due to separate estimation of the solid.

the conversion to a volatile step may be the first stage in the metabolism of fluoride and that it may be a general one for plants. The formation of fluoroacetate would then be caused by a special mechanism in the plants which carry out this step.

If plants in general can contribute to the air around them in vivo one or possibly more volatile compounds containing fluorine, it is fortunate that such compounds. though anaesthetic in high concentration, are on the whole non-toxic. This has been proved for gases like vinyl fluoride4,6.

We thank the Wellcome Trustees for grants, Professor F. G. Young for facilities and our colleagues and Professor Emeleus for many useful discussions. We also thank Mr L. R. Murray for seeds from Alice Springs, and Dr Silvester for supplying the fluoride-18.

IMMUNOLOGY

Increased IgG Synthesis during the Induction of Immunological Paralysis in Adult Guinea-pigs

It is well known that after immunological stimulation, animals produce non-specific gamma globulins as well as specific antibody1. Quantitative studies have shown that injection into guinea-pigs of an antigen mixed with Freund's adjuvant causes a marked increase in the serum concentrations of γ_1 and γ_2 globulins, only part of which can precipitate with the antigen2. On the other hand, the induction of immune paralysis in adult guinea-pigs is accompanied by a transient immunological unresponsiveness to unrelated antigens. A possible explanation for this phenomenon could be that immunological paralysis may start by a defective commitment of immunologically competent cells, which does not result in the production of specific antibody. The aim of the present work was to find out whether the induction of paralysis also results in an increase of γ_1 and γ_2 globulins which might account for some kind of commitment of the competent cells.

Random bred adult guinea-pigs weighing 350-500 g were divided into groups and given daily intraperitoneal injections of bovine serum albumin (BSA) according to the following schedules; group 1, 200 µg/day for 12 days; group 2, 100 mg/day for 20 days; and group 3, 1 g/day for 25 days. Blood samples were collected before the beginning of the treatment (day 0) and then at regular intervals. In all groups, including the control group, an immunizing injection of BSA (I mg) mixed with complete Freund's adjuvant was given to both hind foot pads on Serum anti-BSA titres were determined by passive haemagglutination using bisdiazotized benzidine BSA conjugated to rabbit red blood cells4. The γ1 and γ₂ globulin content in the serum samples was determined by the antibody-agar plate technique⁵ as described before2. The results reported are the average values of the analysis of mixed sera (5 to 10) of each group of animals.

In normal adult guinea-pigs the serum content of γ_1 globulin is roughly one-tenth of that of γ_2 globulin, that is 1 mg/ml. and 10 mg/ml., respectively (Fig. 1, day 0). Under the influence of the daily treatment with various amounts of BSA, the serum content of both γ_1

and γ_2 globulins increases progressively until day 30 and then declines. Although the percentage increase of Y1 globulins is much more important than that of γ_2 globulins, the absolute production of γ_1 is about half that of γ_2 globulins: (1) 2.5 mg/ml. versus 5.5 mg/ml.; (2) 4.5 mg/ml. versus 8 mg/ml.; and (3) 7.5 mg/ml. versus 10.5 mg/ml. in the various schedules of treatment. It is apparent from these figures and from Fig. 1 that the total increase of IgG in the treated animals was proportional to the total quantity of BSA used in the treatment.

Irrespective of the amount of BSA injected, in no case did the treated guinea-pigs produce anti-BSA antibody which could be detected either by Ouchterlony plates or

by passive haemagglutination.

On day 45 all the treated animals as well as a control group were again injected with BSA (1 mg) mixed with Freund's complete adjuvant. This injection resulted in a moderate increase of both γ_1 and γ_2 globulins in the control group (Fig. 1d), and also in the appearance of high titres of haemagglutinating antibody. This secondary injection of BSA produced much lower passive haemagglutination titres in the animals of groups I and 2, showing that a degree of partial paralysis had been induced in these animals by pretreatment with the same antigen. Only in group 3, which had been treated with 1 g of BSA each day for 25 days, was a complete and long lasting state of immune paralysis achieved. In the partially tolerant animals, the challenging injection of BSA produced a fresh increase of γ_1 and γ_2 globulins, comparable with that produced in the control animals. In the completely tolerant animals, however, no such increase was produced and the concentration of γ_1 and γ_2 globulins continued to diminish down to the physiological level (Fig. 1c). It seems likely therefore that "non-specific" γ_1 and γ_2 globulin production is a regular sequel of specific antigenic stimulation and is only suppressed if the animal is fully tolerant to that antigen.

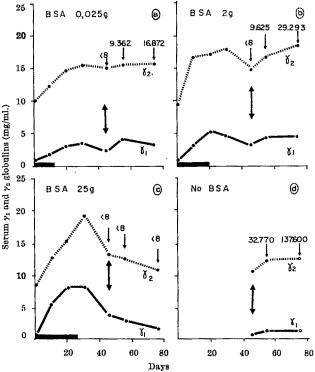

Fig. 1. Effect of treating guinea-pigs with various quantities of BSA on serum γ_1 and γ_2 globulins. \blacksquare , Duration of treatment; \spadesuit , injection of BSA (1 mg) mixed with Freund's adjuvant; 1. passive anti-BSA haemagglutination titre (for further explanations see text).

It is unlikely that the gamma globulins produced during primary treatment and which lack anti-BSA specificity are antibodies directed against impurities contained in the BSA solution. Immunoelectrophoretic analysis of experimental sera tested against whole bovine serum detected only two weak lines of precipitation in the region of alpha globulins. On the other hand, precipitin tests carried out with these serum samples and bovine serum remained negative or very weakly positive. It is known that the limiting sensitivity of these techniques is about 15-30 μg/ml. of antibody protein. This quantity, compared with the 10-20 mg/ml. of new gamma globulin production, leaves little doubt that the main quantity of new-formed gamma globulin is not antibody to the antigen(s) injected. It is also improbable that the administration of BSA provoked an increase in the bulk of natural antibodies, because a secondary type response elicited by unrelated antigens has never been clearly demonstrated.

Injections of Freund's complete adjuvant without added antigen in rabbits have caused a very large increase of 7S gamma globulin. Tests carried out on these sera and a large number of antigens showed that only a small part of the newly formed gamma globulins could be characterized as antibody. Although this gamma globulin may not bear any specific combining site, this must be "virtually unprovable".

Several authors have reported that the injection of sensitizing amounts of soluble proteins often results in induction of immune tolerance rather than in antibody The present findings, although they production8,9. confirm these observations, clearly show that animals regularly respond to these injections with a new production of gamma globulins. Furthermore, this production is proportional to the total antigen given during the primary treatment. It seems therefore that whether the injection of soluble antigens results in antibody production or in immune paralysis, it regularly stimulates lymphoid cells to the hyperproduction of gamma globulin molecules. Perhaps what is decisive in specific antibody production is the form in which the antigen is presented to the lymphoid cells. Recent work indeed suggests that the passage of protein antigen through macrophages greatly enhances the extent of antibody production in a primary response¹⁰, whereas antigen presented in non-phagocytosable form directly produces immune paralysis¹¹. results do not contradict this assumption, but suggest that non-immunogenic antigens can still stimulate animals as evidenced by the production of non-specific gamma globulins, although optimal conditions for antibody production are not met.

Loss of Interferon Activity from the Medium of Cell Cultures producing Interferon

THE time course for the production of interferon in various types of cell cultures has been reported before¹⁻⁴. For example, Heller³ found that chick embryo fibroblast-like (CEF) cell cultures infected with chikungunya virus began producing detectable amounts of interferon 3 h after infection. Thereafter, the concentration of interferon increased linearly for the next 21 h, reaching maximum yield 24 h after infection. We have followed the time course of interferon production in CEF cell cultures infected with chikungunya virus, but were more interested in the ultimate fate of the newly synthesized interferon after the maximum yield had been reached.

CEF cell cultures were prepared by the method of Lindenmann and Giffords slightly modified. The production of interferon was induced by infecting the cell cultures with 2 ml. of a 1:100 dilution of stock chikungunya virus produced in mouse brains and subjecting the cultures to a temperature of 37° C. The medium used consisted of Gey's balanced salt solution without serum, 0.11 per cent (w/v) sodium bicarbonate, 0.1 per cent (w/v) yeast extract (Difco), 0.1 per cent (w/v) proteose peptone and 0.1 per cent (w/v) lactalbumin hydrolysate. At various times after infection, the medium from two cell cultures was removed, pooled and stored at 3° C until interferon could be assayed. Before assay, the fluids were kept at 65° C for 30 min to inactivate the virus which was present in the preparation. Interferon was assayed by using the vaccinia virus plaque-reduction method described by Lindenmann and Giffords. One unit of interferon (PDD_{50}) is described as that amount of interferon needed to reduce the number of vaccinia virus plaques to 50 per cent of the number found on control cultures which had not received any interferon.

Production of interferon could be detected as early as 2 h and continued to be produced until 20-24 h after viral infection (Fig. 1). Thereafter, there was a rapid loss of interferon activity from the medium during the next 24 h, followed by a much slower loss for the remainder of the experiment. The initial rapid loss of interferon activity proceeded at a minimum rate of 0.340 U/h/10⁶

cells followed by further loss during the next 72 h at a rate of 0.066 U/h/106 cells. The overall rate of loss of interferon activity was 0·150 U/h/10° cells. Fig. 1 also shows that interferon was not produced when the CEF cultures were inoculated with chikungunya virus that had been heat-inactivated at 65°C for 30 min. No significant interferon activity was detected in the culture medium from uninfected cell cultures.

Several experiments were conducted to determine if this loss of interferon activity was caused by proteolytic enzymes present in the culture fluid. Fluids containing interferon were collected from cell cultures infected with chikungunya virus for 62 and 120 h. Each sample was divided into two aliquots. One aliquot from each sample was heated at 65° C for 30 min and assayed immediately for interferon activity. The remaining aliquots were placed in a waterbath at 37° C for 9 h before heating to 65° C and assaying for interferon. The results of the assays for each of the two aliquots for a given sample were comparable within 4 per cent, which demonstrated the absence of degradative enzymes in the culture medium.

It is interesting to note that the initial rate of loss of interferon activity from the cell culture medium (0.340 U/h/106 cells) is comparable with the rate of uptake of interferon by cells in culture (0.330 U/h/106 cells) (our unpublished work). Thus it seems reasonable to assume that the loss of interferon activity from the culture medium of cells producing interferon is caused by the adsorption of this same interferon by some of the cells in the monolayer, if not by all of them. This loss of interferon would not become apparent until production of interferon had either ceased or slowed down to such an extent that the rate of adsorption exceeded the rate of production.

We thank Mrs P. Jones and Miss K. Moore for technical assistance. This work was supported by grants from the National Institutes of Allergy and Infectious Diseases, National Institutes of Health, US Public Health Service.

PATHOLOGY

Hormonal Pregnancy Tests and Congenital Malformation

DURING a survey of babies born with meningomyelocele or hydrocephalus, one hundred mothers of such children provided histories of the relevant pregnancy. other things they were questioned by one of us (I. G.) as to the drugs which they had taken. The same information was obtained from a matched control group of one hundred mothers recently delivered of healthy Data obtained from the mothers about drugs during pregnancy were checked with the medical advisers. As part of the survey the mothers were asked how their pregnancy was diagnosed. Nineteen mothers in the survey group and four of the control mothers reported having received oral tablets for the diagnosis of pregnancy (Table 1). There was no significant difference between the two groups with respect to any other drugs taken in the first trimester. The average interval between conception and test was 5.6 weeks in the survey group, and 6.2 weeks in the control group.

	Table 1		
	Pregnancy test	No test	
Survey cases	19	81	
Controls	4	96	
	$2^2 > 6.635$	P < 0.01	
	(1 degree of freedom)		

The age of the mothers is shown in Table 2. The survey mothers were on average some 2 yr older than the controls, and there were more older and younger mothers among those who had been given the pregnancy test. Mothers over 35 years of age are more liable to have infants with a malformed nervous system1, and so the tests of significance were repeated leaving out those cases over 35. A high level of significance remained (P < 0.01).

Defects such as meningomyelocele originate before the closure of the neural canal and fusion of vertebral laminae during the second to eleventh week of intra-uterine life. The tests were administered at this time, the tablets most commonly used being 'Primodos' and 'Amenorone Forte'. The recommended dose is one tablet daily for 2 successive days in the case of 'Primodos' and for 3 successive days in the case of 'Amenorone Forte'. If the patient is not pregnant withdrawal bleeding should occur 3 days after the last tablet is given. The test depends on imitating the normal menstrual cycle during which there is an elevation of circulating progesterone and oestrogen followed by a fall which results in menstrual bleeding. Each tablet of 'Primodos' contains 10 mg of norethisterone acetate and 0.02 mg of ethinyloestradiol. 'Amenorone Forte' contains 50 mg of ethisterone and 0.05 mg of ethinyloestradiol. These doses are claimed to be safe and the test, which was introduced in 1953 by the intramuscular route and in 1956 by the oral route, has been considered free of danger if used on women who prove to be pregnant. It is used very frequently. Contraceptive pills. which have been subject to a very careful scrutiny, have a similar composition, but the dose and balance of the constituents are different; for example. 'Norlestrin' contains 2.5 mg of norethisterone acetate and 0.05 mg of ethinyloestradiol. Any effect of these pills on the foetus comparable with that suggested for the pregnancy test would be limited to cases in which they were taken by already pregnant women.

		Table 2		
Maternal	age (yr)	< 20	20-35	> 35
Survey	Test	2	13	4
	No test	5	66	10
Control	Test	1	2	1
	Ma toot	0	88	6

The possibility cannot be excluded that the difference significant at the 1 per cent level between the two groups of mothers whom we questioned might emerge purely by chance. Nevertheless, our observations indicate the need for a more detailed scrutiny of the role of hormonal preparations in the causation of congenital malformations. particularly when taken in the organogenic stages of pregnancy. Full details of this work will be published elsewhere.

Induction of Tumour Immunity with Tumour Cells treated with Extract of Garlic (Allium sativum)

It is generally believed that in some conditions tumour cells act antigenically, and that immunization of the host animal prevents tumour growth on subsequent challenge with virulent tumour cells. One of the most important problems in this field is to find a suitable and effective method to obtain attenuated tumour cells which still Recently, two effective possess their antigenicity. techniques were reported—the use of irradiated tumour cells1 and the use of tumour cells treated with iodoacetate²—and Ishidate³ has used nitrogen mustard N-oxide for this purpose.

We have found that pretreatment of tumour cells with an extract of garlic (Allium satirum) is effective and that mice injected with these cells developed strong immunity to the same type of tumour cells. One volume of fresh, unwashed Ehrlich ascites tumour cells was mixed with the same volume of extract of freshly ground garlic (5 g of ground garlic extracted with 25 ml. of distilled water) and incubated for 1 h at 37° C. The mixture was centrifuged at 800g for 5 min and the sediment was washed once with two volumes of physiological saline and then suspended in one volume of the same solvent. suspension (0·1 ml.) containing $5 \times 10^6 \sim 10^7$ cells was injected intraperitoneally into mice (strain DDD).

In the initial experiment, we found that tumour cells which were pretreated with an extract of fresh garlic did not produce ascites tumours and no mouse died during the observation period of 10 weeks. In contrast, both tumour cells pretreated with an extract of garlic that had been boiled before grinding and tumour cells incubated in physiological saline alone produced ascites tumours in all mice, which died 2 or 4 weeks after intraperitoneal injection.

Table 1. Effect of garlio extract on immunogenic capacity of ehrlich ASCITES TUMOUR CELLS

Materials	No. of attenuating treatments	Time of challenge after the last treatment (days)	Mortality after Challenge
Physiological	meannemo	or casmons (days)	
saline (control)	1 (i.p.)	7	10/10
Tumour cells treated with	2 ,,	14	10/10
fresh garlic	1 ,,	7	9/10
,,	1	14	8/10
**	2 .,	7	8/10
,,	2 ,,	14	0/10
1.0	2 (s.c.)	14	0/10

In another experiment, we found that when mice were treated twice at intervals of 7 days with freshly prepared tumour cells exposed to the extract of fresh garlic, they acquired resistance against a challenge with Ehrlich ascites tumour cells. None of the mice developed ascites tumours or died within a period of 100 days even though 10⁵ live fresh Ehrlich ascites tumour cells were injected 14 days after the second treatment with cells exposed to garlic. All control mice challenged with the same number of tumour cells developed ascites tumours and died within 2 or 4 weeks. Subcutaneous injection of the attenuated tumour cells gave similar results. The results are summarized in Table 1.

Although the mechanism by which immunity is achieved when cells are attenuated with extract of fresh garlic is not yet clear, it is known that garlic contains allicin which derives from alliin by the action of alliinase, as elucidated by Stoll and Seebeck⁴. Because allicin reacts with sulphydryl groups of tumour cell proteins^{5,6} it is not improbable that our technique is based on similar actions of garlic extracts on ascites cells.

Chromosomal Constitution of Meningiomas

NUMERICAL and structural chromosome anomalies have often been reported in human tumours. It is not known whether the change from normal to tumoral cells is induced by or followed by a disturbance of the chromosome complement. Neither is it known whether all chromosome aberrations develop at the same time, or whether any special type of aberration induces further disturbances. Cytological and cytogenetical studies of benign tumours are thus very important; they may well give more information about the mechanism of cell transformation.

The tumours were cultured by the method of Kersting¹. The medium used for 600 brain tumour cultures did not allow excessive growth of connective tissue. Chromosome analysis was carried out on primary particle cultures in roller tubes. Cultures grown for 5-9 days were subjected to a hypotonic treatment in citrate solution. The cells were fixed in glacial acetic acid and methanol (1:3), air dried and stained with aceto-orcein. Well spread metaphases from between five and fifteen cover slips were photographed under phase contrast.

Table 1 shows the cytogenetic observations and their correlation with the morphology of the meningiomas. A striking similarity can be seen in the basic type chromosomal aberrations; in all eight tumours a G-group chromosome is missing. In four tumours additional chromosomes are missing, and in one case a C-group chromosome is supernumerary, resulting in a final chromosome count of forty-six. The pathological chromosome complement is uniform for every tumour. As well as the aberrant stemline there is a stemline with a normal number of chromosomes. One of the eight meningiomas has three different stemlines. Hyperploid cells were absent except for a few tetraploid cells deriving from the pathological as well as the normal stemlines. Structural anomalies like breakages, translocations or other reunion figures were very rare. Only a very tight end to end association of different chromosomes was often found. In 7-15 per cent of the mitoses there was a varying hypoploidy and in most of these cells the membrane was broken. The basic karyotype of forty-five, XX (or XY), G-, corresponded to an isomorphic endotheliomatous psammomatous meningioma with many whorls and onion skin-like structures and psammomatous bodies. The two tumours with only forty-two chromosomes can be classified as fibromatous meningiomas. The prolifera-tion pattern in tissue culture was not clearly different from that of the other tumours. After 10-12 days an accessory fibroblast-like cell type used to appear in most of the cultures, particularly in the marginal zone.

Benign tumours other than meningiomas usually have either a normal diploid chromosome complement or a non-systematic loss or gain of chromosomes which varies from cell to cell, with a tendency to hyperploidy. Most of the meningiomas which we studied were a mosaic of normal and abnormal cells. The abnormal cell strain was hypoploid and homogeneous in one tumour. This homogeneity suggests that these cells had a common origin.

The basic chromosome aberration in our meningiomas is the loss of a small acrocentric chromosome, accompanied in four out of eight tumours by further numerical aberrations. There were no essential structural abnormalities in any chromosomes. A similar situation is well known in chronic myeloic leukaemia, where the only aberration is the partial loss of a G-group chromosome. Atkin and Taylor² have reported a case of chronic myeloic leukaemia with a Ph^1 -chromosome and another missing G-chromosome in about 60 per cent of the cells. Ishihara³ found in a case of gastric cancer the partial loss of a Ggroup chromosome as an isolated chromosome aberration. Van Steenis⁴ and Simons⁵ calculated on the basis of the karyotypes published by Makino⁶ and Ishihara^{7,8} that in hyperploid tumours only the G-chromosomes are not

·-·-, Hypoploid chromosome complement; cell membrane probably broken (see text).

usually augmented, which results in a relative reduction of G-chromosome material. Kiseleva $^{\circ}$ suggested that loss of G-chromosome material could be related to uncontrolled cell multiplication. This does not agree with our own findings, for our meningiomas showed increased but not uncontrolled cell multiplication.

The occurrence of a varying percentage of cells with a normal karyotype suggests that cells with an aberrant chromosome complement's could stimulate the surrounding normal cells to an excessive proliferation and to produce different histological structures in relation to the karyotype of the inducing cell. This would mean that the cytogenetically identifiable "tumour cells" in a meningioma may only be a part of such a tumour.

Peroxidation of Lipid from Paroxysmal Nocturnal Haemoglobinuria-like Erythrocytes

ERYTHROCYTES from patients with paroxysmal nocturnal haemoglobinuria (PNH) are lysed excessively by agents which peroxidize lipid, and their lipid forms more lipid peroxides than that of normal erythrocytes^{1,2}. Recently we noted that incubation of normal red blood cells in reduced glutathione results in cells with all the usual in vitro lytic features of "natural" PNH cells. In the work reported here we have compared lipid extracts from red blood cells of normal subjects and patients with various haemolytic disorders with those of "natural" and "induced" PNH cells, with respect to peroxidation.

Blood samples drawn by venipuncture from six normal laboratory personnel, from patients with various types of haemolytic anaemia and from four patients with established PNH, were defibrinated in sterile containers using glass beads. After centrifugation at 3,000 r.p.m. for 10 min and removal of serum and buffy coat, the red blood cells were washed three times with physiological saline. Washed normal erythrocytes (14 ml.) were incubated at 37° C in 56 ml. of a solution of reduced glutathione (210 mg/ml. at pH 8·0) by shaking in a 50 ml. Erlenmeyer flask at 60 oscillations/min for 15 min. Control samples of washed normal red cells incubated in saline solutions of comparable ionic strength and pH were simultaneously carried through all procedures. After incubation, the red cells were centrifuged at 3,000 r.p.m. for 10 min, the supernatant removed, and the cells washed three times with physiological saline.

Selected in vitro lytic features of PNH erythrocytes are shown in Table 1. Normal red cells incubated with reduced glutathione were indistinguishable from red cells of patients with PNH. The optimum pH for acid-serum lysis was the same for "natural" and "induced" PNH red cells—6.0

Lipids of control red blood cells (including samples from normal subjects and patients with haemoglobinopathies, immune haemolytic anaemia, spherocytosis and glucose-6-phosphate dehydrogenase deficiency) and "natural" and "induced" PNH red cells were then extracted as described by DeGier et al.3. Washed cells (4 ml.) were haemolysed to a final volume of 25 ml. with water. The final chloroform layer was evaporated to dryness at 37° C under vacuum and the residue collected in a final total volume of 9 ml. of physiological saline. The lipid extract was analysed for total phosphorus and used immediately4. Lipid extracts so obtained were white and opalescent and no gross differences were observed between the groups studied Quantities of lipid extracted from each batch of cells (as lipid phosphorus) did not vary, and thorough mixing of the lipid extract "suspen-

sion" before sampling resulted in reproducible concentrations of lipid.

Portions of lipid extract (2-4 ml.) were shaken at 100 oscillations/min in 100 ml. quartz Erlenmeyer flasks 11 cm below an ultra-violet source (General Electric G15-T8) for 2 h. After incubation, 2 ml. of the extract was mixed with 2 ml. of 10 per cent trichloroacetic acid and filtered through Whatman No. 3 paper. A sample of the filtrate (1 ml.) was then mixed with 1.2 ml. of 0.67 per cent thiobarbituric acid, heated in a boiling water bath for 15 min, allowed to cool to room temperature and the absorbance read at 535 mu. Tetraexthypropane (which hydrolyses to ethanol and malonylaldehyde) was used in the thiobarbituric acid reaction as a standard and lipid peroxides were expressed as mμmoles malonylaldehyde/μg lipid phosphorus.

As Table 2 shows, the lipid of "induced" PNH cells formed greater quantities of lipid peroxides more rapidly than lipid from control cells and at concentrations comparable with those of "natural" PNH red blood cells. All patients with PNH had normal serum tocopherol concentrations and normal red blood cell glucose-6-phosphate dehydrogenase, catalase and glutathione peroxidase activities.

These studies show that normal red cells incubated with reduced glutathione acquire the in vitro lytic features which are used to classify "natural" PNH red cells. In addition, the lipid of these cells behaves like the lipid of "natural" PNH cells with respect to lipid peroxidation. The fact that lipid of "natural" and "induced" PNH cells formed greater quantities of lipid peroxides more rapidly than that of control cells during exposure to ultra-violet light provides additional evidence that lipid peroxidation is involved in the basic intracorpuscular defect of PNH.

RADIOBIOLOGY

Protection of Canine Pancreatic Ultrastructure against Radiation Damage by Post-treatment with Alloxan

In a previous study we demonstrated that pretreatment of dogs with a single small, non-diabetogenic dose of alloxan monohydrate (15 mg/kg) intravenously protects the pancreatic ultrastructure against severe irradiation damage.

In non-alloxanized dogs the irradiation by a single, large dose of roentgen rays (5,000-9,000 r.) of the exteriorized pancreatic remnant after partial surgical pancreatectomy produced extensive cellular damage characterized by widespread focal cytoplasmic degradation, alterations of endoplasmic reticulum and mitochondria, and reduction in size and number of mature zymogen granules2-4. Pancreatic amylase, leucine aminopeptidase and lipase activities showed a marked decrease in these animals. After alloxan, however, ultrastructural alterations induced by irradiation were not observed apart from occasional minor lesions¹. On the other hand, the marked reduction in the activities of pancreatic tissue enzymes noted after irradiation alone was also found in the dogs pretreated with alloxan.

In addition to the series of twenty-nine irradiated dogs pretreated with alloxan1, we have also examined five dogs which were given alloxan several days after radiation treatment, and three more dogs which received alloxan both before and after irradiation. Table 1 lists the radiation and alloxan doses, the various time intervals and the pancreatic tissue enzyme changes in these dogs; a summary of the observed ultrastructural alterations is given in Table 2. The methods for partial pancreatectomy and radiation treatment were identical with those previously described2,3.

Severe changes, similar to those observed in irradiated but not alloxanized animals, were not seen

When they were examined with an electron microscope no severe or extensive cytological alterations were found in any of the eight dogs (Table 2), especially when compared with two large series of similarly irradiated animals which had not been pretreated with alloxan²⁻⁴. observed lesions, however, though neither severe nor widespread, were somewhat more prominent that those seen in the pretreated irradiated dogs. At any rate, it is evident from these data that alloxan arrests many otherwise observable post-irradiation changes of the cytoplasm of the canine pancreas, even when administered as late as 1 or 2 weeks after irradiation.

These observations are in keeping with a recent com-munication by Doolittle and Watson⁵, who reported that alloxan, when administered to mice within a few hours after exposure to X-rays, reduced the level of mortality induced by radiation below that of mice which received saline solution instead of alloxan. There was a decrease in the tissue activities of three important pancreatic enzymes (Table 1), however, which was in keeping with a similar decline of enzyme activity after irradiation alone²⁻⁴, alloxan pretreatment plus irradiation¹ or alloxan treatment alone1

The rationale for the radioprotective action of alloxan, whether administered before or after irradiation, as well

as for its depressive effect on pancreatic tissue enzyme activities, is not known. It might be explained by the hypothesis that its interaction with amino-acids modifies the structure and reduces the synthesis of proteins, particularly those with free amino-acid groups or radicals 6-8.

The post-treatment of dogs with a single, small nondiabetogenic dose of 15 mg/kg of alloxan monohydrate protects the pancreatic ultrastructure against severe irradiation damage. A decline of pancreatic activity of amylase, lipase and leucine aminopeptidase, however, occurs. We suggest that the radioprotective action of alloxan on the pancreas may be due to the reduction of protein synthesis induced by alloxan and to its known effect on amino-acids and —SH radicals⁶⁻⁸.

PHYSIOLOGY

Molecular Sieving by Glomerular **Basement Membrane**

Or the three layers of the glomerular capillary wallendothelial cells, basement membrane and epithelial cells—the basement membrane appears to be the only complete barrier between the plasma and the glomerular filtrate1,2. Support for the view that the basement membrane is the most important filtering mechanism was provided by the studies on ferritin transfer across the glomerular capillary wall²⁻⁵. Graham and Karnovsky⁶ have concluded that the epithelial slits are the primary

filtration barrier and suggested that glomerular basement membrane acts only as a "coarse" filter. It is thus still not established whether the basement membrane acts as a filter.

The nephrotic syndrome is characterized by increased permeability of the glomeruli to serum proteins and consequent proteinuria. Paradoxically, the permeability is associated with an increase in thickness of the glomerular basement membrane⁷⁻⁸. Movat, Steiner and Huhn¹⁰ suggested that in acute glomerulonephritis a decrease in density of the basement membrane presumably associated with hydration and separation of the constituents could account for the increased permeability. Similarly, on the basis of chemical composition and X-ray diffraction patterns11,12, it was concluded that the membrane thickening in experimental nephrosis might be caused by molecular rearrangement of the membrane components so that the interstices between molecules become larger and permit passage of large molecules such as plasma proteins. If this explanation is correct, the normal and nephrotic membranes are analogous to dextrans of greater or lesser degree of cross linkage, and should show similar molecular sieving effects.

Rat glomerular basement membrane was prepared by a modification of the procedure of Krakower and Greenspon¹³. Nephrosis was produced by three daily injections of rabbit antiserum to whole rat glomeruli. The animals which showed high proteinuria (> 200 mg/24h) 2 weeks after the first injection were used for experiments.

Suspensions of basement membrane particles in 0.9 per cent saline were allowed to settle by gravity in small chromatographic tubes to give columns 1.5×60 mm. Columns packed with 'Sephadex G-25' were used as controls. A solution containing albumin- ^{131}I and mannose-¹⁴C (10 μl.) was applied to each column, the column was washed with 0.9 per cent saline and the cluate was collected in fractions of 10 μl. with capillary glass tubes. Carrier albumin and mannose were added to each fraction. The protein was precipitated with 10 per cent trichloroacetic acid, dissolved in 2.5 normal sodium hydroxide and assayed for iodine-131 in a well scintillation counter. The supernatant containing mannose-14C was assayed for carbon-14 in a liquid scintillation counter.

The elution patterns of protein and mannose from the columns are given in Fig. 1. As anticipated, albumin, being excluded from the 'Sephadex', was eluted well ahead of the mannose. The column of normal basement membrane produced a small but definite retention of the mannose relative to the albumin. Thus basement membrane from normal glomeruli produced a molecular sieving effect.

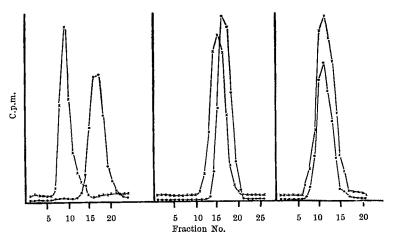

Fig. 1. Elution patterns of albumin-¹³¹I (×) and mannose-¹¹C (♠) from microcolumns. From left to right: 'Sephadex G-25', glomerular basement membrane from normal rats and glomerular basement membrane from nephrotic rats.

When basement membrane from nephrotic rats was used, there was complete overlap of the albumin and mannose peaks, indicating that albumin was retarded to the same extent as mannose. The elution volume of albumin from the column of nephrotic membrane was smaller than that from the column of normal membrane. Attempts to determine the void volume of membrane columns using 'Blue Dextran 2000' were unsuccessful because the dextran was adsorbed by the membrane. It is known that the void volume of 'Sephadex' columns varies with the degree of cross-linkage and that the void volume of a column of 'Sephadex G-25' may be equal to or even greater than the elution volume of a material which is retained on a column of less highly cross-linked 'Sephadex'. This phenomenon probably explains the small elution volume from the column of nephrotic membrane.

These results are compatible with the hypothesis that renal glomerular basement membrane acts like 'Sephadex' in separating large and small molecular species and that in nephrosis the basement membrane behaves like a more porous, less highly cross-linked 'Sephadex'. It seems likely therefore that basement membrane acts in vivo as a differential filter and that in nephrosis the basement membrane is more permeable because of a more open molecular structure.

Suppression of Oestrous Behaviour in the Immature Male Rat

THE neonatal testis of the rat is responsible for suppressing the capacity of the nervous system to mediate female sexual behaviour. Male rats castrated on the day of birth and treated with ovarian hormones as adults display oestrous behaviour; if castration is performed after the first post-natal week, female sexual behaviour is greatly

Neonatally castrated rats have not been tested for oestrous behaviour before 80 days of age1-4. The possibility therefore remains that rats castrated at the end of the first week of life and treated with ovarian hormones at the time of testing display greater sexual receptivity before puberty than post-pubertally. This hypothesis is supported by evidence that action of neonatal androgens on sexual differentiation of the brain does not take complete effect until after 60 days of age. For example, ovaries transplanted into male rats at the time of castration-5-6 days after birth-contained fresh corpora lutea and ripe follicles when the animals were killed between 39 and 61 days of age; ovaries removed from

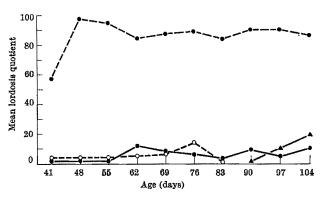

Fig. 1. Female sexual behaviour in rats treated with ovarian hormones.

. Males castrated on day 7 (group 1); A—A, males castrated on day 27 (group 2); O - - - O, males castrated on day 27 (group 3);
. - - O, females ovariectomized on day 27 (group 4).

similarly prepared males killed about 120 days of age contained follicles but no corpora lutea⁵. Similarly, female rats treated with androgens shortly after birth exhibit ovarian cycles for a few weeks beginning at 70 days of age and only subsequently develop the syndrome of anovulatory sterility6.

Four groups of rats were used: groups 1 and 2 contained, respectively, twelve and eight males castrated 7 days after birth; group 3, eight males castrated 27 days after birth; and group 4, ten females ovariectomized at 27 days of age. Groups 1, 3 and 4 were tested for oestrous behaviour beginning at 41 days of age and group 2 beginning at 90 days of age.

To induce receptivity each rat was injected subcutaneously with 6 µg of oestradiol benzoate and 40 h later with 0.4 mg of progesterone. Seven hours after the progesterone injection, each animal was placed in a cage with three stimulus males for 3 min or until it had been mounted six times^{7,8}. The number of times each test animal was mounted and the number of lordoses elicited by these mounts were recorded. The ratio of lordoses to mounts ×100 (lordosis quotient) was used as the index of sexual receptivity. Successive tests were separated by one week.

Male rats castrated at 7 days of age do not display lordosis frequently, either before or after puberty (Fig. 1). Animals in group I generated uniformly low lordosis quotients regardless of their age at the time of testing. Action of the neonatal testis in suppressing lordosis is complete by the seventh post-natal day; males in group 1 were not more receptive at any age than males castrated on day 27 (group 3). All male castrates displayed lordosis less frequently than the female castrates (P < 0.01) on each of the weekly tests. This confirms and extends earlier findings1.

Female rats first develop full behavioural responsiveness to ovarian hormones at 30 days of age. The failure of males to display lordosis may have been due to their advanced age (41 days) at the time of the first test. To test this possibility six male rats were castrated 5 days after birth and an equal number on the seventh day of life. Tests for oestrous behaviour were given at 26 days of age and again at 33 days. These young rats were mounted only infrequently; in no case was lordosis observed. Oestrous behaviour is therefore observed only rarely in male rats castrated later than the fifth day of life, regardless of the age at which tests are initiated.

In conclusion, suppression of the neural substrate for oestrous behaviour in the male rat is induced by the fifth day of life and does not depend on a post-pubertal maturational process. Suppression of female sexual behaviour follows a different time course from inhibition of the female pattern of gonadotrophin release; the intact male hypothalamus cannot mediate oestrous behaviour at a time when it can apparently support the cyclic female pattern of gonadotrophin release. For behaviour, then, the male nervous system functions in the stable manner of adulthood beginning very early in life, whereas, for regulation of gonadotrophin secretion, "all hypothalami are of the female type during a significant part of the life span and . . . action of androgen . . . in the neonatal period does not take effect until some time after puberty"5.

This work was supported by the Committee on Research, University of California. I thank F. A. Beach for reading the manuscript and the Schering Corporation for the supplies of hormones.

Voltage Clamp Studies on Snail (Helix aspersa) Neurones

Investigations of snail neurones have shown that some cells can maintain their action potentials in solutions free of sodium1-4 and are not affected by tetrodotoxin3. These nerves may have a calcium carrying current system similar to that described in barnacle muscle⁵.

We have used a system where the whole membrane of the snail neurone perikaryon can be clamped at a specified voltage without showing any notching or oscillations in current⁶, and the preparation showed a current waveform similar to that described by Hodgkin and Huxley' for the squid axon.

In Fig. 1, curve A shows the maximum inward current plotted against membrane potential and curve a shows the steady-state outward current, when the cell is in

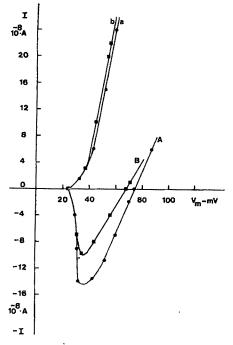

Fig. 1. Current-voltage relations of the membrane of a neurone of Helix aspersa. A. Maximum inward current in normal Ringer; B. maximum inward current in sodium-free Ringer; a. steady-state current in normal Ringer; b, steady-state current in sodium-free Ringer.

normal Ringer (sodium, 80 mmolar; calcium, 7 mmolar). When the external solution was replaced by a sodium-free Ringer there was still an inward current (curve B) although this was less than that seen in normal Ringer. inward current was found even in neurones washed in sodium-free solution for 20 min. When the solution was replaced by normal Ringer, the full inward current was restored after about 100 sec.

The reduced inward current seen in sodium-free solution disappeared if the cell was placed in a solution containing neither sodium nor calcium. Although the reduced inward current seen in sodium-free solution could be increased by replacement of sodium, the reduced current could not be restored by an increase of calcium up to seven times the normal value. Cells injected with EDTA showed a normal inward current in standard Ringer but not in sodium-free Ringer containing calcium.

The inward current of cells in normal Ringer was not reduced by tetrodotoxin in concentrations between 10-9 and 10-5 g/ml. The inward current in sodium-free solution could be abolished by charging the membrane at 30 mV or higher and maintaining this potential for more than 20 min. The current was re-established when the cells were replaced in normal Ringer.

There may be a small store of sodium ions closely associated with the nerve membrane (either trapped in the glia or in the folds of the membrane, or even actually in the membrane structure) which cannot be easily removed by washing in sodium-free Ringer but which is affected by the calcium ion concentration.

We thank the Science Research Council for a grant towards the apparatus.

Amnesia induced by Scopolamine and its Temporal Variations

An anticholinesterase drug, diisopropylfluorophosphate (DFP), has been reported to produce weak amnesia for habits learned 30 min before its intracerebral injection, no amnesia for habits learned 3 days before and considerable amnesia for habits 5 and 14 days old1. There is also no amnesia for habits learned I day before injection of this drug (unpublished results of Deutsch and Stone). One of the effects of DFP is to slow down the destruction of the transmitter acetylcholine, thus permitting it to accumulate, and so DFP may block conduction at a synapse. This action would particularly affect a synapse where the amount of acetylcholine ejected during transmission is high, because accumulation sufficient to cause a block would in this case be quickly reached.

The temporal variations in amnesia induced by anticholinesterase have therefore been interpreted2,3 as showing that after the learning experience there is a gradual change in the level of transmitter ejected by a synapse during transmission. This level would be high immediately after learning (during temporary storage) and would drop rapidly to a low point, from which it would slowly increase to a new high level (underlying the long-term memory of a habit).

This hypothesis was tested in an experiment paralleling the one using DFP already reported, but injecting the

anticholinergic drug, scopolamine, instead, An anticholinergic agent reduces the effectiveness of acetylcholine and would therefore block transmission to the greatest extent at synapses where the concentrations of this transmitter are low. This is the opposite of the action of an anticholinesterase. If the inferences concerning transmitter output are correct, the reverse effect of the one described should be obtained using a drug with an anti-cholinergic action. The use of the anticholinergic, scopolamine, should produce greatest amnesia where the effect of DFP was least and have its smallest effects where the effects of the anticholinesterase were greatest. This would support the hypothesis that the level of chemical transmitter output varies with age of memory. Such a prediction is supported by some other preliminary

Male rats (Sprague Dawley, Rockland strain, 350 g) were trained to a criterion of ten consecutive correct choices to escape shock to their feet by running to the lighted arm of a Y-maze, the position of the light changing randomly, as described before. Five groups of rats were then injected with scopolamine intracerebrally under 'Nembutal' anaesthesia in a stereotaxic instrument. The first group was injected 30 min after learning, the second at 1 day, the third at 3 days, the fourth at 7 days and the fifth at 14 days. The animals were included in each of the groups on the basis of initial learning scores, so that the groups were matched on the basis of initial learning. The placement of the bilateral injection was anterior 3, lateral 3, vertical +2; and anterior 3, lateral 4.75, vertical -2, according to the atlas of DeGroot⁶. Peanut oil (0.01 ml.) containing 0.58 per cent of scopolamine was injected in each placement. Twenty-four hours after the injection, the rats were retrained to the same criterion. This gave a measure of the relative amount of retention of the various groups.

The results of the experiment are shown in Table 1. The maximum amnesic effects were found on habits acquired 1 day (group 1) or 3 days (group 3) before injection. A specific comparison between the mean relearning scores for groups 2 and 3 combined and all other groups was found to be statistically significant $(F=10\cdot42, df=1/35, P<0\cdot01)$ as revealed by an analysis of variance. A reduction of effect for the 3 day group (group 3) appears, compared with the 1 day group (group 2). In the case of DFP no effect is seen at 1 or 3 days, both groups having scores indistinguishable from peanut oil controls.

The design of the DFP experiment does not allow us to see whether the minimum effect of DFP on memory is at 1 or at 3 days after training, and this makes accurate comparison with the effects of scopolamine uncertain. An additional test (Mann-Whitney-U) of the difference between the median relearning scores of groups 1 and 2 was found to be significant at P < 0.01. It can be seen that the amnesic effect obtained with scopolamine shows an initial increase followed by a decline, this being the opposite of the DFP effect, although of about the same time course.

predicted, scopolamine produced its greatest amnesias for habits of the ages where the effects of DFP were least and had its smallest effects where the effects of the anticholinesterase were greatest. results therefore support the hypothesis that the effective physiological basis of memory is a change in synaptic conductance, mediated by an increase in the concentration of effective transmitter, in this instance probably Such a change in conductance, once acetylcholine.

			Table 1			
Group	Time to injection after initial training	N	Mean trials to criterion initial training	Mean trials to criterion relearning	Standard deviation	Median trials to criterion relearning
1	30 min	8	22.25	11.88	15.87	7.5
2	1 day	8	24.38	23.88	14.59	20.0

Secretions from the Lateral Scent Glands of the Green Vegetable Bug, Nezara viridula

GREAT interest attaches to the division of biosynthetic activities between the different types of cell in a gland complex and to the mechanisms whereby toxic secretions are prevented from causing harm during synthesis and storage. The scent gland complex (Fig. 1) of Nezara viridula var. smaragdula (F.) consists of a median ventral metathoracic scent reservoir, which is orange yellow in colour, and of paired colourless lateral glands sometimes called accessory glands. The lateral glands discharge through ducts into the reservoir, which also receives secretions from the gland cells which form its epithelium. The multicomponent secretion stored in the reservoir is used in defence and the gland complex resembles that of other Pentatomid and Coreid1,2 bugs.

The secretions from the reservoir cells cannot be obtained for separate examination uncontaminated with the stored scent, but it is possible to isolate the lateral glands and examine their composition. Table 1 shows the compounds extracted with 2-propanol from lateral glands collected in Canberra and in Hawaii. Excised glands from 20-100 insects were steeped in a few µl. of 2-propanol and the extract analysed by gas chromatography⁸ on columns of 'Apiezon L' and didecyl phthalate by comparison of retention times with those of authentic compounds. Lateral glands of bugs from Hawaii were moistened with 2-propanol during transport in sealed tubes and were several days old before analysis. Besides known scent components, these extracts had an additional unidentified component, not present in stored scent or shown in Table 1, which increased on further standing and therefore appears to be a storage artefact.

N. viridula is a cosmopolitan species. We have shown previously³ that of scent collected from the storage reservoirs of Australian specimens the principal constituents comprise n-alkanes, alk-2-enals, alk-2-enyl acetates and 4-keto-hex-2-enal. Comparison in Table 1 of the principal components of the scents from the storage reservoirs of insects in Hawaii and insects in Canberra shows that

both these scents are very similar in composition. They contained none of the C, alk-2-enal reported4 for the scent of this species from Louisiana, USA.

The proportions of scent components are very different in the lateral glands and in the storage reservoir. The hydrocarbons, particularly n-tridecane, are much less abundant in the lateral gland extract and must therefore be assumed to be synthesized chiefly by the reservoir gland cells. Indeed, it is possible that the hydrocarbons which find their way into the gland extract may not be produced in the lateral glands because, in other experiments, tridecane and dodecane were detected in 2-propanol extracts of lateral glands of the coreid, Amorbus rubiginosus (Guerin). Hydrocarbons are not present in the stored scent of this insect2 and thus these alkanes in the lateral glands may be characteristic of the cytoplasm of the gland rather than of the contents of the discharge

The principal component of the lateral gland extract is decenyl acetate, which is present in the extract at up to twenty times its percentage in the stored scent. Decenal, on the other hand, is much less abundant than in the scent. It is possible that the small amounts of decenal and hydrocarbons are the result of their diffusion back from the scent reservoir for some distance into the larger ducts of the lateral glands. When fat body adjacent to the lateral glands was extracted and examined in the same way as the lateral glands, no scent constituents were detected.

In unpublished data on the defensive secretions of a number of stink bugs, we have observed that the presence of an aldehyde in the scent is usually associated with the presence of some of the acetate of the corresponding alcohol. We have also suggested that the biosynthetic pathways of the two series of compounds are linked. Thus Commius elegans (Donovan) which has a Nezara type scent composition (chief odour component: decenal) also has a preponderance of decenyl acetate in extracts of lateral glands, but only a trace of decenal. In the bronze orange bug Musgraveia sulciventris (Stal) the principal odour component is oct-2-enal and extracts of lateral glands contained octenyl acetate, together with tridecane and a trace of dodecane.

The present results indicate that the alkenyl acetates are produced in the lateral glands. The duct from each lateral gland branches in a racemose fashion, the finer branches being surrounded by groups of secreting cells. Because these glands lie free in the haemocoele their secretion is seemingly less well isolated from the haemolymph than are the contents of the scent reservoir. We suggest that the highly reactive and toxic aldehydes may be subsequently formed within the relatively impermeable storage sac itself.

PSYCHOLOGY

Myers-Briggs Type Personality Scales and their Relation to Taste Acuity

SENSITIVE quinine taste responders, that is, subjects with low taste thresholds for quinine and other compounds the taste thresholds of which also follow a Gaussian distribution in a population, are more particular in their choice of food1,2, react earlier and in response to smaller doses of systemic stimulants3 or tranquillizers4 and display faster reaction times as measured by the serial There are also significantly fewer heavy seven test⁵. cigarette smokers among sensitive quinine responders as a group if contrasted with an age and sex-matched population of subjects with high quinine taste thresholds1,6.

The work reported here was conducted in an attempt to determine whether personality type is related to a The Myers-Briggs type subject's taste threshold. indicator7 was selected because it is a brief, self-report inventory which results in simple continuous scores on four scales of dichotomous Jungian personality types: extroversion-introversion (E-I), sensation-intuition (S-N), thinking-feeling (T-F) and judging-perceiving (J-P).

Fifty-five college students in the Department of Anthropology of the Ohio State University, 19-29 years old (mean age, 20), were administered the Harris-Kalmus⁸ forced-choice, double blind taste threshold test with our modification *,10. Because the cumulative effect of age and smoking on taste thresholds is not apparent at the age level of our subjects6, it was not necessary to control for smoking.

The Myers-Briggs was administered only to subjects at the extremes of the log normal distribution of taste thresholds, consisting of very sensitive tasters, with thresholds 2-3, and the very insensitive, with thresholds 6-7, assuming that in the middle range of sensitivity other factors could interfere with a relation between taste acuity and personality.

On the sensation-intuition scale, sensors (S), as a group, were found to be taste insensitive, whereas intuitors (N)belonged to the taste sensitive group (see Table 1). The means of the continuous scores were 85.2 for the sensitive tasters and 63.6 for the insensitive tasters, with higher scores in the direction of intuition. The value for t = 2.00(using Student's t test) is almost significant at the 0.025 level for a one-tailed test and at the 0.05 level for a twotailed test. Because the relation was predicted on the basis of earlier data¹⁻⁵, the one-tailed test is justified.

The Myers-Briggs Manual describes personality patterns based on scores on all four scales, whereas we obtained a difference only on one, the S-N dimension. Because we have separated the scores for those properties which reflect this dimension, the available descriptions will be less specific than if they had been measured separately.

According to MacKinnon¹¹, in the United States three out of four show a preference for the actualities of sense perception while the remainder prefer the possibilities of intuitive perception. In contrast to an estimated 25 per cent of the general population who are intuitive, 90 per cent of the creative writers, 92 per cent of the mathematicians, 93 per cent of the research scientists and 100 per cent of the architects are intuitive as measured by this test.

On the other hand, Vandenberg12 believes, based on research performed with 27 fraternal and 40 identical twin pairs, that the distinctions measured by the Myers-Briggs scales with the exception of extroversion-introversion apparently are not based on hereditary factors but presumably reflect environmental influences. own quinine taste threshold studies with Kaplan¹³ with 70 dizygotic and 75 monozygotic twin pairs show that the within pair variance for dizygotic and monozygotic twins, combining like sex pairs, is significant for the P < 0.05 level indicating a small but definite role of heredity in taste threshold for quinine and other Gaussian compounds. These data may appear to conflict with Vandenberg's conclusion, in that a significant difference between taste sensitive and insensitive groups was not found on the extroversion-introversion scale. On the contrary, we prefer to suggest that the present day American culture tends to encourage extroversion and sensation and that this cultural influence may be particularly strong in overshadowing any predispositions to introversion and intuition in the taste sensitive subjects of our sample of mid-western "middle-class" college students. A study with very rich or very poor older subjects might prove or disprove our hypothesis.

In summary, as a group, insensitive tasters are factual down-to-earth organizers, whereas sensitive tasters are theoreticians with insight who follow their inspirations.

Selective Action of Pentobarbital on a Multiple Schedule of Reinforcement

Many demonstrations of the sensitivity of behaviour to drugs in a variety of situations have established the importance of environmental factors in determining drug behaviour interactions1. More specifically, patterns of responding that are differentially sensitive to drugs can be obtained by arranging different schedules of reinforcement² or by manipulating the parameters of a particular contingency3.

Hearst⁴ studied the effects of pentobarbital on behaviour within a system for classifying reinforcement schedules in terms of temporally defined parameters. The system defines two basic variables: t^D and t^Δ time periods during which a reinforcement can be obtained or is never obtained, respectively. During operation of the schedule, the durations of t^D and t^Δ are kept constant, they are alternated and only the first response to occur in t^D is reinforced. When, within a 30 sec cycle, t^D is decreased progressively from 30 to 0.4 sec a transition from "interval-' to "ratio-like" behaviour is observed. Hearst, using these contingencies in a multiple schedule to generate both response rates separately in individual rats, found that "ratio-like" behaviour was relatively insensitive to pentobarbital at a dosage of 8 mg/kg, although the drug increased response rates on the component generating "interval-like" behaviour. The present experiment extends Hearst's observations and examines also the effects of pentobarbital on behaviour produced by a schedule in which low rates of responding are differentially reinforced

Three adult male albino rats, which had not previously been used in experiments, were maintained at 80 per cent of their free feeding weights and exposed to a multiple schedule of reinforcement for 40 min daily during 5 months. The soundproof test chamber was equipped with a lever and a Gerbrands feeder which dispensed 45 mg food pellets as reinforcement. Depression of the lever activated counters and a cumulative recorder. equipment and electronic timers controlled the experimental arrangements automatically.

After magazine training⁶ and several sessions of continuous reinforcement, the animals were transferred to a multiple schedule consisting of two components which alternated for a total of eight 5 min periods in each session, each component being separated from the next by 1 min in which no contingency was operative. During component 1, behaviour was maintained on a schedule consisting of 15 sec DRL and 5 sec LH, that is, each depression of the lever was reinforced only if preceded by a minimum pause of 15 sec and a maximum pause of 20 sec timed from the preceding response. On component 2, reinforcements were available according to the system employed by Hearst with the following parameters: rat 1 was exposed throughout to a cycle length of 20 sec in which $t^D = 5 \sec (\tilde{T} = t^D/t^D + t\Delta = 0.25)$; rats 2 and 3 were exposed throughout to a cycle length of 10 sec in which $t^{\bar{D}} = 0.3$ sec $(\bar{T} = 0.03)$ and $t^{\bar{D}} = 0.15$ sec $(\bar{T} = 0.03)$ 0.015), respectively, these values being attained over a period of 75 days in which tD was reduced progressively from 5 sec ($\overline{T} = 0.5$). A red light and masking noise accompanied component I; noise was absent and a white light illuminated the chamber for component 2. After the response rates on each component had become stabilized, intraperitoneal injections of pentobarbital were given at intervals of 3-4 days in dosages ranging from 1-8 mg/kg. Each injection (control injections of distilled water were also given) was made 10 min before the commencement of a given session. The pentobarbital supplied contained 60 mg/ml. of pentobarbital sodium, 10 per cent alcohol and 20 per cent propylene glycol in sterile water. Carlton' reported some insensitivity of operant behaviour in rats to a mixture of pentobarbital and these alcohols, compared with an equivalent dose of pentobarbital dissolved alone in water.

Figs. 1A, B and C show representative cumulative records of behaviour generated by the components of the schedule before the drug was given; component 1 appears on the left and component 2 on the right for each rat. During component 1, low, stable rates of responding characteristic of DRL contingencies were obtained after

between seventy-five and eighty sessions. On average, subjects made twenty-three responses and secured between nine and twelve reinforcements during 5 min although each rat showed a characteristic pattern of collateral behaviour which intervened between responses. On component 2, it is evident that rats 2 and 3 responded appreciably faster than rat 1, thus affording general confirmation of Hearst's findings that marked increases in rate were observed when t^D was reduced to a small proportion of cycle length and when, as a consequence, the number of reinforcements obtained decreased. Whereas rats 2 and 3 responded on average at corrected rates of 110.9 and 115.2 responses/min ("ratio-like" behaviour), rat I gave a corrected mean rate of 65.5 responses/min, missing hardly any reinforcements, and displaying evidence of "scalloping" in the cumulative record ("intervallike" behaviour).

When low doses of pentobarbital were given, no reliable effects of the drug were observed. For doses of 1-5 mg/kg, it was found that the first time a given dose was administered rates of responding on component I tended to increase while, with the exception of rat 3, rates of responding on component 2 decreased. observations were unreliable, however, because a second administration of the same dose of the drug 3-4 days later frequently did not affect behaviour on one or both components consistently. It is worth noting therefore that at low doses any effect of the drug was transitory for one or both components of the schedule and to this extent the findings agree with those of Hearst, who failed to obtain clear effects at a dosage of 4 mg/kg.

When the drug was given repeatedly in a dose of 8 mg/ kg the selective effects on behaviour shown in Figs. 1D, E and F were observed consistently. Pentobarbital exerted an excitatory effect on behaviour maintained by component 1, that is, the distribution of inter-response times, characteristic of efficient DRL performance, was affected markedly by an increased incidence of responses occurring in close temporal proximity to one another. The effect is in agreement with results reported by Sidman⁸ and may be partially attributable to lack of motor co-ordination which impaired specific patterns of collateral behaviour. For example, rat 1 developed a consistent tendency to rear onto its hindlegs and to move backwards and forwards in this manner between responses. Pentobarbital impaired rearing, simultaneously increasing the rate of lever-pressing.

On component 2, results inconsistent with those of Hearst⁴ were obtained, for overall rates of response were reduced by the drug as compared with control sessions, the effect being more pronounced the higher the rate engendered by T. The results are summarized in Fig. 2

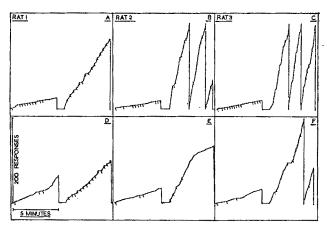

Fig. 1. Sample cumulative records showing the behaviour of each animal under control (A, B and C) and drug (8 mg/kg pentobarbital: D, E, F) conditions. Component 1 (DRL) is shown on the left and component 2 (Hearst contingency) on the right in each compartment of the figure. The control record appears above the drug record for each animal, respectively. Oblique marks denote reinforcements.

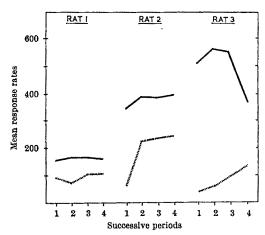

Fig. 2. Response rates for 5 min periods on component 2 of the multiple schedule under control (——) and drug (----) (8 mg/kg pentobarbital) conditions.

and do not support the contention that "ratio-like" behaviour is relatively insensitive to the drug (rat 3) as compared with "interval-like" behaviour (rat 1) at a dose of 8 mg/kg, although at doses of less than 5 mg/kg this may have been true if consistently reliable effects of the drug had been observed.

We may note, in conclusion, that, although the results obtained are at variance with those of Hearst, procedural differences distinguish the two experiments. are in agreement, however, with those of Sidman's for component 1 and are consistent with those of Waller and Morse⁹ for component 2 if the behaviour of rats 2 and 3 can be regarded as resembling fixed-ratio performances. Waller and Morse reported that low dosages of pentobarbital (2-4 mg/kg) in pigeons increased response rates engendered by a low-valued, fixed ratio schedule (FR 30); at higher dosages, however, the drug (5-6 mg/kg) produced decrements in rates of responding, indicating that insensitivity to drug effects cannot necessarily be viewed as a general property of behaviour maintained by ratio contingencies.

Markovian Models of **Dialogic Time Patterns**

THE duration histograms of pauses and vocalizations in continuous speech have the form of negative exponentials1. For example, the shortest audible pauses are most numerous and the frequency at each longer pause interval is some fixed proportion of the frequency at the next shorter interval. This implies that the probability of prolonging a given pause is constant, regardless of the elapsed time in the pause. The same holds true for duration of vocalizations. The future of the temporal sequence is then stochastically determined by the present and is independent of its history.

Considering pause and vocalization to be the two "states" of monologue, regular sampling yields a sequence of state transitions in successive enquiries. When adjacent samples are found to be in the identical state, the process is assumed to have remained in that state during the intervening interval. The data reported here were sampled at a rate of 200/min (ref. 2). Such a time series can be described as a finite Markov chain, that is, a stochastic process which moves through a finite number of states and for which the probability of entering a certain state depends only on the last state occupied3.

Analogous treatment of the temporal pattern of dialogue yields a sequence of transitions among four dyadic (two person) states. They are: both speakers silent (state 0); A speaks and B is silent (state 1); B speaks and A is silent (state 2); and both speak (state 3). The temporal pattern of a dialogue may then be described as a sequence of the states zero, one, two, three. Because the duration histograms of these dyadic states are also exponential4, a finite Markov chain is a reasonable model for the time pattern of dialogue.

To test the fit of the model, one may compute certain necessary mathematical consequences. For example, the time series of dyadic states may be summarized by the transition matrix P of equation (1).

$$P = \begin{bmatrix} p_{00} & p_{01} & p_{02} & p_{03} \\ p_{16} & p_{11} & p_{12} & p_{13} \\ p_{20} & p_{21} & p_{22} & p_{23} \\ p_{30} & p_{31} & p_{32} & p_{33} \end{bmatrix}$$
(1)

The rows of P are the states at any time t, the columns are the states at time t+1, and the elements p_{ij} the conditional probabilities of moving from state i at t to state jat t+1. P is a stochastic matrix, the rows of which each sum to 1. One consequence of the model is that the probability of reaching any state j from any state i is given by the ijth term of the nth power of matrix P. We have shown that these higher order transition probabilities are indeed approximated by this computation. Another consequence computable from matrix P corresponds to a commonsense feature of dialogue, that is, the time between "switches" of speaker. A new switch is defined the first time a speaker vocalizes alone (states 1 or 2) following any sample in which the other speaker has been the sole The state sequence between switches correvocalizer. sponds to the intuitive phenomenon of "holding the floor". In Markovian terms, it is the mean waiting time in a set of states before absorption, and varies from 3 to 10 sec in our recorded dialogues.

The estimates under the Markovian hypothesis are then correlated with the actually observed mean switching The model predictions so computed for a series of 200 experimental interviews yielded an average product moment correlation of 0.93 (ref. 5). Such concentration of information about long range events (3-10 sec) in short range transition probabilities (300 msec) implies that the latter are quite stable, or approximately stationary.

Two criteria for preferring a particular stochastic model of behaviour are its parsimony and theoretical intelligibility. From this standpoint, the model described is not very parsimonious in that twelve parameters are necessary to account for sixteen transition probabilities: three elements of each row of matrix P define the fourth. Furthermore, the model offers no hypothesis as to the way in which the separate speakers interact to generate

this temporal sequence. Our purpose here is to test one hypothesis about the interaction of speakers which may account for the Markovian property observed. It can be characterized as an "independent decision" hypothesis, and was suggested to us by Professor Alex Heller, of the City University of New York.

Let q_i = the probability that speaker A vocalizes at time t+1 given dyadic state i at time t; r_t = the probability that speaker B vocalizes at time t+1 given dyadic state i at time t; $1-q_i$ = the probability that speaker A is silent at time t+1 given dyadic state i at time t; and $1-r_i$ = the probability that speaker B is silent at time t+1 given dyadic state i at time t. (i = 0, 1, 2, 3.)

From these assumptions a Markov chain can be generated, as summarized in matrix \tilde{P} of equation (2).

$$\widetilde{P} = \begin{bmatrix} 1-q_0 & (1-r_0) & q_0 & (1-r_0) & (1-q_0)r_0 & q_0r_0 \\ (1-q_1) & (1-r_1) & q_1 & (1-r_1) & (1-q_1)r_1 & q_1r_1 \\ (1-q_2) & (1-r_2) & q_2 & (1-r_2) & (1-q_2)r_2 & q_2r_2 \\ (1-q_3) & (1-r_3) & q_3 & (1-r_3) & (1-q_3)r_2 & q_3r_3 \end{bmatrix}$$
(2)

Note that \widetilde{P} is also a stochastic matrix, the rows of which each add up to 1; however, there are only four parameters for each speaker.

If the matrix P of equation 1 is taken to be the maximum likelihood estimate under the hypothesis that the process is a Markov chain, then it can be shown that the maximum likelihood estimates for the q_1 and r_1 are

$$q_1 = p_{i_1} + p_{i_3}$$
 and $r_1 = p_{i_2} + p_{i_3}$ $(i = 0, 1, 2, 3)$

As a test of the combinatorial hypothesis, matrix \tilde{P} was generated for sixty of the two hundred interviews of the previous study, and the Markovian predictions of mean speaker switching durations were repeated as before. The correlation of the actual with the predicted mean speaker switching times for the "independent decision" hypothesis was 0.80, thus accounting for the temporal sequence almost as well as did matrix P, albeit with eight as opposed to twelve parameters.

To the extent that this independent decision model fits, it suggests that speakers in these interviews act independently of each other at any given instant, but always with a probability which is dependent on the joint behavioural configuration of the immediately prior instant. Furthermore, it suggests that these transition probabilities are relatively stable, so that a 300 msec history is sufficient to account for the temporal pattern of the vocal interaction.

BOOK REVIEWS

TRANSLATED WITH COMMENT

Celestial Mechanics

By Laplace. Translated with a commentary by Nathaniel Bowditch. Vol. 1: Pp. 168+xxiv+746. Vol. 2: Pp. xviii+990. Vol. 3: Pp. xxix+910. Vol. 4: Pp. xxxvi+ 1018. (Bronx, N.Y.: Chelsea Publishing Company, Inc., 1966.) \$79.50 the set of four volumes.

Among the proliferation of reprints of older works which has become quite a feature of the book market, the issue, in a facsimile of high quality, of Bowditch's translation of the Mécanique Céleste makes widely available one of the most remarkable productions in the astronomical literature.

The importance of the French original needs no emphasis. It was intended to be much more than an elaboration of the Newtonian theory of the solar system: it purported to lay the foundation for an all-embracing, purely dynamical description of the material universe, considered as an ensemble of particles interacting by central forces. In striving towards this ambitious aim, Laplace had to extend in every direction the methods of which Newton had laid the foundations, and which Euler and his followers had already considerably refined. On one hand he sharpened the mathematical tools, especially the theory of differential equations and series expansions, and on the other hand he gave the principles of dynamics a more systematic and more complete expression. Every step of his progress was a response to some challenging problem presented by the celestial phenomena, and the picture of the "system of the world" gradually emerged in conjunction with a continual deepening and widening of the powerful method of analysis which we now call theoretical This monumental treatise, conceived on an encyclopaedic scale, was rightly regarded by contemporaries, not only in France but in the whole scientific world, as the source from which every physicist had to draw. The flourishing schools of theoretical physics founded in Germany by Gauss and in Britain by W. Thomson have their origin in Laplace's inspiration. Not only his methods, but his general conception of science-Laplacian determinism—moulded the natural philosophy of the nineteenth century.

In the British and German universities, there was no great demand for a translation of a book written in French. In England, however, science was actively studied by a large number of people barred from the universities by class prejudice or religious intolerance, and who needed textbooks in their own language. To translate Laplace's treatise in its entirety was too formidable a task, but there appeared in 1816 a translation of the first book, comprising the exposition of the laws of mechanics. It was this translation that introduced the miller's son George Green of Nottingham to the Laplacian methods he so brilliantly extended. In America, the social basis of scientific studies was very similar: the colleges were primarily religious institutions, and active scientific work was carried out by practical men. Nathaniel Bowditch was one of them, by trade a sailor, learning the art of navigation the hard way, and completely autodidactic with respect to its scientific foundations. In 1802, he published The New American Practical Navigator, a manual which went through eight editions. He wrote extensive notes and comments on Laplace's treatise "at the time of reading the volumes, as they were successively published", and he undertook the full translation of the text during 1814 to 1817. With his proud sense of independence and self-reliance, he preferred to set aside the manuscript until he was able to publish it at his own expense, after he had gone into a prosperous insurance business in Boston. The four superb volumes appeared between 1829 and 1839—the last one a posthumous tribute to the indefatigable worker, who had died the year before, as the printing was nearly completed. The typographical execution is a masterpiece, which does honour to early American craftsmanship; one sympathizes with the craftsman's pride expressed in the mention "Ira Berry and Lucius A. Thomas, compositors" unobtrusively printed at the end of the first volume, and a similar one at the end of the second volume. It is an antiquarian rarity, for only 250 copies were printed.

The work itself is much more than a translation; indeed, the extent of Bowditch's own contributions equals, or perhaps exceeds, that of the translation proper. It is well known that Laplace wrote with extreme concision, and was even in the habit of disposing of intricate or unconvincing arguments by the misleading phrase "it is clear that . . .". Bowditch's commentary restores all the intermediate steps omitted by Laplace with unsparing, sometimes pedantic, explicitness. In long appendices he presents whole treatises on the elementary mathematical methods which the author had assumed to be part of the reader's general knowledge, or on special problems such as the practical computation of orbits, worked out in every detail, with all necessary tables. The notes also contain full accounts of progress subsequent to the publication of the original volumes. The fifth, supplementary, volume of the French edition, which appeared twenty years after the others, is not translated, but most of its content is embodied in the translator's

notes.

A memoir of Bowditch, written by his children, was appended to the last volume; it is now more appropriately placed at the beginning of the first. With its incredibly stilted style, often producing involuntarily caricatural effects, this memoir is a most revealing period piece. It gives a vivid portrait of the industrious commentator, who, putting Laplace with Archimedes in the class of the great creators, compared himself with Euclid, 'a second-rate mathematician"; and it evokes a striking picture of the parochial Yankee society that could foster such extraordinary personalities. L. ROSENFELD

DECIDING BY NUMBERS

Introduction to Probability and Statistical Decision

By G. Hadley. (Holden-Day Series in Industrial Engineering and Management Science.) Pp. x+580. (San Francisco and London: Holden-Day, Inc., 1967.) \$11.85. STATISTICAL decision theory depends on the idea of utility, an idea which sounds as though it could have been borrowed from the world of business. Whether or not it was, there is almost a campaign going on in America to return the loan with interest, by presenting techniques of decision making in the face of uncertainty in forms that emphasize their place in the training of business men. A technique that could determine correct decisions both about building Concord and about rejecting a large batch of radio resistors on the basis of the fraction defective would have to be pretty magical. The fact, however, that the techniques are statistical makes it clear that they will be of more use for decisions like our second example.

The work being reviewed resembles several others in this and related fields, coming from the United States, in that attractively constructed examples are described and worked out in the text, under headings like "The Tomato Soup Company's Problem". Reading the latter example we find data about prior probabilities, costs of various actions, information available about observable random variables, and so on, motivated and supported by a lively story about a production manager who has to decide how many tons of tomatoes to buy. The problem is worked out, with the accompanying story bringing in further data as required, to the conclusion that he should contract for about 375 acres of tomatoes.

Most of the characteristics of the book are exemplified in "The Tomato Soup Company's Problem". decision process described is Bayesian and the production manager in the story firmly adopts a normal prior distribution for the yield of tomatoes, having a mean of 60 tons/acre and a standard deviation of $\bar{4}$ tons. examples are thoroughly numerical, though the figures have surely been organized so that none of the calculations get messy. The text accompanying the calculations is descriptive and colourful, which accounts to some extent for the 580 pages to which the book extends. The length of the book, however, is also due to the large amount of material in it. A reader who has started with finite event sets in the first chapter will be using posterior distributions for jointly continuous distributions by the time he reaches the "Tomato Soup" problem in the eighth chapter, having been taken through a mass of technical material on the way. In connexion with continuous distributions we note that sections using the calculus are specially marked and the book is so designed that a great deal can be read without even this tool. Mathematical topics like the gamma function and $\lim_{p\to 0} (1-p)^{1/p}$ are outlined, although the level is illustrated by the fact that the latter is shown numerically to be "approaching a number whose value is 0.367", followed by a remark about proof, and a reference.

The contents of the book are divided fairly evenly between the two subjects in the title. The first, fifth, sixth and seventh chapters provide a fairly standard treatment of probability theory, from finite event sets up to a statement, without proof, of the central limit theorem. The second chapter introduces the idea of utility, and decision problems are dealt with in the third and fourth chapters. In the eighth chapter the two threads of the book are brought together to deal with "problems which have the characteristic that in determining the probabilities of the states of nature we make use of historical data or personal feelings and, in addition, make use of the results of a random experiment". In the ninth chapter the classical techniques of hypothesis testing and estimation are introduced and their relation with the decision-theoretic methods in the book is outlined. The tenth chapter treats the Poisson process and in the final chapter sequential decision problems are introduced.

This book is stimulating in many ways and in the United States it will clearly be a saleable addition to Holden-Day's series on "Industrial Engineering and Management Science". It is harder to see a place for it in a British university syllabus. It might be useful in a degree course in mathematics and statistics, but most students in such a course would not need the lengthy numerical illustrations and the partial avoidance of calculus. Postgraduate students in operational research would also, probably, have sufficient background to find the pace of this book slow. Nevertheless, instructors in such courses would find it a useful source and a good book to refer some students to after a tutorial. It could well be just the book for self-instruction by someone who decided to take up the subject on his own.

W. A. O'N. WAUGH

SOURCE BOOK OF SEPARATION

Chromatography

By Erich Heftmann. Second edition. (Reinhold Chemistry Textbook Series.) Pp. xli+851. (New York and London: Reinhold Publishing Corporation, 1967.) 220s.

This is the second edition of the book published in 1961 and reprinted in 1963. There has been much revision; obsolete matter has been eliminated while latest developments have been incorporated and several new chapters have been added. The author index has been eliminated, which I think is a mistake, especially because the authors of publications listed at the end of each chapter are not arranged alphabetically. The book is intended as a reference work and also "as a supplementary textbook for graduate school courses in analytical chemistry, biochemistry and chemical engineering". Whether this applies to students or teachers is not clear, but whatever their standard of living in the United States, very few in this country could afford to buy the book.

This book is a collective work with contributions from more than thirty authors, and is organized in two parts. The first deals with theories and techniques of all the forms of chromatography and includes electrophoresis. The second part contains chapters which cover the applications of all these techniques to particular classes of compound. Much of this part covers the literature to 1965, which is a praiseworthy achievement, but some sections do not go so far and consequently are already outdated, examples being gas chromatography of sugars and of amino-acids. Some sections of this second part tend to be highly concentrated reviews which make them rather difficult reading, and I feel that more use could have been made of tables which would have made it easier for the reader to obtain information. This has been done with good effect in the chapters on nucleic acids, phenolics, terpenes, non-hydrocarbon and hydrocarbon gases.

The first part of the book generally reaches a high standard. The two chapters on the general theory of chromatography and on the theoretical basis of partition chromatography are particularly valuable contributions. Techniques are covered adequately and the chapters are well written expositions of principles and practical aspects. This part does not suffer from the shortcomings of the second part which perhaps are inevitable, as one cannot expect a single book to cover such a vast subject fully.

Nevertheless, this volume contains a great deal of useful, comprehensive and up to date information and is probably the best general book on chromatography which exists.

R. Consden

ENVIRONMENTAL RADIOACTIVITY

Radioecological Concentration Processes

Edited by Bertil Aberg and Frank P. Hungate. (Proceedings of an International Symposium held in Stockholm on April 25-29, 1966.) Pp. xiv+1040. (Oxford, London and New York: Pergamon Press, Ltd., 1967.) 300s. net.

MAN began the spread of artificial contaminants through his environment when he lit his first smoking fire, and from this small beginning he has gone on to pollute air, land and water with a wide variety of toxic substances. Five to ten years ago, the contaminant which aroused greatest public alarm was the radioactive fallout from nuclear weapons exploded in the atmosphere. Undoubtedly, some of this alarm was an expression of general unease at the very existence of the weapons, but it did

stimulate many governments to initiate measurements of existing levels of radioactive contamination, and to encourage research into the ways in which the radioactivity reaches the human body. This book contains just over one hundred papers reporting some of the findings. There are contributions from both Europe and America, with a preponderance of papers from Russia, Scandinavia and the United States.

The reader is led to wonder whether any other form of artificial contamination has been the subject of such exhaustive research. Papers contributed to the eleven sessions of the symposium report the concentrations of radioactive isotopes in soil, fresh water and sea water, and describe their metabolism by plants and animals in all three environments. In addition to the detailed reports, there are five review papers by specialists in different branches of the subject.

The isotopes caesium-137 and strontium-90 receive most attention, because they are potentially the most dangerous constituents of fallout, but there are also accounts of work on isotopes such as zinc-65 and chromium-51, which are present in the waste discharged from nuclear reactors, and on iodine-131, which might be released in a reactor accident. The need to understand the biological properties of many radioisotopes gives practical application to some seemingly recondite studies, such as the one concerning the metabolism of chromium-51 by marine worms.

Several papers are devoted to studies on Eskimos and Lapps, for to these people belongs the distinction of having the highest known burdens of caesium-137. In 1965, the average content in each person was about 1 μc., compared with a typical content of about 0·03 μc. in those of us who live in more temperate regions. Eskimos and Lapps acquire these relatively large amounts of activity in reindeer meat, which figures prominently in their diet. The reindeer becomes contaminated with caesium because it grazes on lichens which, in comparison with more rapidly growing plants, are particularly efficient accumulators of the isotope. There are papers from Russia, America and Scandinavia describing in detail the passage of caesium-137 and other isotopes through this

unique food-chain.

In trying to assess the seriousness of artificial radioactive fallout, it is useful to compare its contribution to
the radiation background with that from the natural radioelements, and a group of papers reports work on the
radium and thorium series. The hazard from these natural
sources may not always be negligible. An extreme
example is reported by a Russian worker, who describes
an area with a natural background dose rate some three
hundred times the average, and claims that burrowing
animals show the ill effects of chronic exposure to ionizing
radiations. Another paper in the same group discusses
the observed concentration of stable lead in the environment, and serves to remind us that radioactive materials
are not the only toxic substances which are widely
distributed.

The editors and publishers have succeeded in issuing these proceedings with only moderate delay. The editors explain in their introduction that, to speed publication, the papers are printed as they were received, with only minor alterations. The most noticeable result of this is a serious lack of clarity in a few of the papers translated into English from other languages. In one paper, figure captions have been interchanged, and, in another, two graphs are printed in duplicate, but otherwise the book appears to be free from typographical errors. Its price will not recommend it to the individual, but it should find a place in the library of any institution where work of this nature is in progress. Not only does it contribute to our knowledge of biological mechanisms, but it is also a useful compendium of data on levels of radioactivity in the environment in the years 1958 to 1965.

L. BURKINSHAW.

GONADOTROPHIN CLUB MINUTES

Recent Research on Gonadotrophic Hormones Edited by E. Trevor Bell and John A. Loraine. (Proceedings of the Fifth Gonadotrophin Club Meeting, Edinburgh, 1966.) Pp. viii+345. (Edinburgh and London: E. and S. Livingstone, Ltd., 1967.) 70s. net.

THE Gonadotrophin Club, we are told, met five times during the past thirteen years, but this is the first publication of its deliberations. Thirty-one members from nineteen laboratories were selected to attend, and discussed the following topics in relation to gonadotrophins: bio-assay and immunological assay; chemistry; extraction from urine, blood and tissue; excretion; clinical applications; and biological and biochemical actions. Most space (eighty-three pages) is devoted to clinical applications; the remainder is divided almost equally among the other topics.

Three or four papers are presented on several aspects of each topic. Each group of papers is followed by a short, frank discussion. Editorial revision of the verbatim record and a logical progression through the subject have enabled an extremely readable account of the meeting to be produced.

The papers are of a high standard, as one would expect from the list of participants, and a vast amount of information is presented. It is worth noticing, however, that there are no reports of the action of follicle stimulating hormone at a biochemical level, nor of efforts to examine the control of follicular growth and atresia. Progress in these two particular areas appears to be lagging.

Unfortunately, much of the work described at the meeting had been published previously, or appeared in print before publication of this volume, and will be known to prospective readers. Consequently, one has the impression that little really new work was discussed. This rather detracts from the interest and importance of the book.

The editors achieve a more useful purpose by providing a record of the discussion of each paper. Several papers were presented on most topics, thereby illuminating the different approaches which have been made. A careful study of both papers and discussion will be found rewarding, at least by those with some familiarity with the subject.

On balance, this volume provides a useful summary of the state of research on gonadotrophins in early 1966, and illustrates the different opinions held in the various centres around the world. Those who need a concise, readable account of current thinking on this subject will do well to refer to this book.

NEUROTIC BACKGROUND

Neurosis in the Ordinary Family

A Psychiatric Survey. By Anthony Ryle. (Mind and Medicine Monographs.) Pp. 156. (London: Tavistock Publications, Ltd.; Philadelphia and Toronto: J. B. Lippincott Company, 1967.) 32s. 6d.

One of the great problems of psychiatry is to discover the background of neurosis. Although in examining a patient we take a full history, we can rarely obtain other than a vague and tenuous picture of the environment behind the illness. Moreover, the facts we obtain are often distorted or insufficient and only severe neurosis in parents and grandparents strikes the informants as being worth mention. Slighter conditions are glossed over and frequently the whole background is blurred by prejudices, carelessness or stupidity. It is important, therefore, that not only neurotics but their families should undergo complete psychiatric examination. The person to perform this work successfully is more likely to be the general practitioner than the consultant. He knows the families, and may, indeed, have treated other relatives before the

presentation of the patient. It is not easy to mislead him or hide facts.

This excellent little book is an attempt to show the personal relationship of 112 working-class families. The clinical information regarding the patient is considered in relation to information obtained by a social worker, questionnaires filled in by the parents, and reports obtained from the children's schools.

The picture is built up by examining the social circumstances, the parents' backgrounds, neurosis in the parents themselves, their marriages, child rearing practices, psychological disturbances in the children, and the parental factors associated with them, family diagnosis and treatment.

It is impossible in a short space to describe all that has been unearthed. It is clear, however, that marital adjustment depends to a great extent on the presence of neurosis in the parents and this is later reflected in the personalities of the children. Although the author states that "the relative importance of nature and nurture remains uncertain", in spite of all his work, there is no doubt that the presence of a poor environment tends to produce fresh generations of neurotics, and so on in an endless chain.

The fact that evidence of any marked fall in the neurosis rate with age does not seem to exist contradicts the suggestion, which has been made in some quarters, that neurosis tends to recover spontaneously without treatment. The illness of civil life does not follow the recovery pattern shown in war neurosis.

This book is worth reading and obviously records a great deal of social and clinical work. It is unfortunate that the final chapter on evaluation and conclusions is not clearer, for it needs a great deal of searching to discover the implications of this research. CLIFFORD ALLEN

GENETICS OF MENTAL ILLNESS

Humangenetik

Ein Kurzes Handbuch in Fünf Bänden. Herausgegeben von P. E. Becker. Band V/2: Psychiatrische Krankheiten. Bearbeitet von H. Bickel, H. Cleve, G. Koch, W. Lenz, E. Strömgren und E. Zerbin-Rüdin. Pp. xvi+613. (Stuttgart: Georg Thieme Verlag, 1967.) 190 D.M.

This volume is in the best tradition of the German handbuch, with encyclopaedic coverage of the world literature, a detailed summary and critical analysis of former publications (including both large surveys and reports of single cases), and a synthesis of widely scattered information into a coherent whole. The neuroses are considered by Strömgren in the only contribution from outside Germany, a delightful essay but without the minute documentation found elsewhere in this book. Lenz deals with the autosomal abnormalities associated with mental deficiency; a valuable summary of many individual case reports but, perhaps inevitably, lacking the generalizations that one expects after the collection of so much material. In the chapter on inborn errors associated with mental deficiency, Bickel and Cleve are equally at home with the clinical, genetical and biochemical aspects of the various disorders. Koch reviews the epilepsies, a field where the slow identification of distinct genetical categories is only just beginning, and where genetical analysis is correspondingly difficult.

The most complex problems are those offered by schizophrenia, manic-depressive illness, and the organic dementias; here diagnosis is difficult, there is no clear segregation between affected and non-affected, and no assistance from biochemical characterization. The assessment of previous investigations is a hard task, for varying diagnostic criteria and selective factors render them hazardous to compare. Zerbin-Rüdin has risen magnificently to the challenge; previous investigations are summarized, their

findings tabulated (and occasionally, where appropriate, re-arranged) and their conclusions keenly examined. In this way a vast collection of information about these disorders has been digested, and the conclusions have been presented in a most readable fashion. The review of the literature is remarkably complete, and includes a full discussion of important papers published as recently as last year. These chapters are the highlight of a volume that will be indispensable for all students of psychiatric genetics.

R. T. C. Pratt

MILK IN THE HUNGRY COUNTRIES

Milk Production in Developing Countries By R. O. Whyte. Pp. 240. (London: Faber and Faber, Ltd., 1967.) 50s. net.

This most interesting survey of the conditions necessary for increasing the production and use of milk in the developing countries provides the first comprehensive and practical account of the problems met with in this type of endeavour to improve standards of nutrition, particularly of children and other vulnerable groups of the population.

Many of the existing milk production schemes in such countries stem from the extensive work, starting shortly after the end of the Second World War, of the UN Children's Emergency Fund (UNICEF). Rehabilitation of milk production, conservation and consumption in the devastated countries of Europe, most of which had had a dairy industry of some importance before the war, was the first objective. Later, usually in conjunction with the UN Food and Agriculture Organisation (FAO), the attempt was made to tackle the more difficult task of beginning or extending, in underdeveloped countries with a hungry population, the indigenous production and processing of milk to provide a safe, high-protein, supplementary food. UNICEF funds met the cost, and its engineers made the selection, of suitable modern processing plant and equipment; governments undertook to house these in appropriate buildings provided with the essential services and close to actual or potential sources of an adequate milk supply. While UNICEF sent in experts to erect and manage the processing dairies until indigenous staff could be trained to take over, FAO provided advisers to assist in the improvement of local fodder production and dairy husbandry. Governments also agreed that, in the distribution of the processed milk, the special needs of young children and nursing mothers should be given priority.

In most of the European countries that received aid from UNICEF, milk production and distribution were fairly quick to recover; in most of the underdeveloped countries, with a very primitive milk industry-or none at all-progress was, not unexpectedly, much slower. The basic difficulty of producing sufficient milk, within an operable distance of a processing plant of economic size, in order to keep the plant working efficiently throughout the year sometimes proved, with its associated logistics and incentives, impossible of solution. Inadequate water supplies, poor roads and transport, ignorance of dairy husbandry among the suppliers, shortage of trained farming advisers and of processing staff were among the handicaps which confronted most of these enterprises in their early days and still do today. It is surprising that, despite these difficulties, several countries in the Near, Middle and Far East, in Africa and in Latin America are making good progress with their milk nutrition schemes.

This book not only gives a detailed, penetrating and up to date account—not by any means confined to the countries benefiting from FAO and UNICEF support—of the essential requirements for improved milk production in warm and in tropical countries, but also records the various degrees of achievement already attained in several of them. The author, with his long experience in India and

the East, provides an authoritative assessment of most of the problems which have a direct bearing on milk production, whether geographical, soil and climate, grassland, fodder, animal husbandry, or economic. This assessment should be of special value to the advisers of such governments of developing countries as are genuinely interested in the nutrition of their children and of their population generally, and who are willing to do something about it.

Dr Whyte's analysis and well-documented proposals, which he supports by figures which are probably as near the mark as statistics from underdeveloped countries are likely to be, will meet with little criticism from those with experience of these countries. He gives two numerical items, however, which catch the eye: on page 167 "over 80 per cent of the milk produced in India comes from buffalces"—this is surely a misprint; the figure given recently by other authorities is between 55 and 60 per cent. In describing milk production in Tunisia on page 136, 5,000 dairy cattle and 130,000 dual purpose cattle are mentioned, but nothing is said about the 380,000 buffalces¹ which must also contribute substantially to the Tunisian milk supply.

H. D. KAY

¹ FAO Production Yearbook, 19, 190 (1965).

INSECT ECOLOGY

The Ecology of Insect Populations in Theory and Practice

By L. R. Clark, P. W. Geier, R. D. Hughes and R. F. Morris. Pp. xiii + 232. (London: Methuen and Co., Ltd.; distributed in the USA by Barnes and Noble, Inc., 1967.) 45s.

This book, written by four experienced insect ecologists from different continents, cannot and does not fail to be extremely valuable. It is recommended at some stage of their careers to all who are interested in insect ecology.

A combination of authors, however, in ironing out each other's opinions, also carries the possible hazard of underemphasis in striking a line for the uninitiated. For this reason the reader must either start with opinions which the book will undoubtedly modify, or be patiently prepared to read repetitively in order to erect a basic and biased set of opinions from which further consideration can lead to true appreciation.

The system adopted in this book of presenting, often usefully by quotation rather than mere reference, a set of diverging opinions followed by a discussion, is attractive but may in some cases be spoiled by a lack of final opinion especially if the reader is a beginner. A more extensive treatment would have been welcome in spite of the comment in the preface that principles only would be discussed.

The two introductory chapters are excellent in clarifying the idea of the "life system" approach to the greater dynamic equilibria. Similarly, the third chapter, "Current Theories to explain Insect Numbers", is a really fine précis of a voluminous literature. It is true that there is scope here for disagreement, that quotation is selective and does not bring out this or that point, but by and large a good bird's-eye view emerges.

On the other hand, the fourth chapter, "The Functioning of Life Systems" (89 pages), is at once interesting and all important, but to some people will be slightly exasperating. Certain readers would prefer a more unified approach to each case, possibly summarized by diagrams and followed by an overall discussion, whilst others, including myself, would prefer it as it is. In any case, however, the references are ample and the wide selection of types reviewed is gratifying. This chapter must constantly be reviewed because herein lies the "proof of the pudding". Never is this more true than when reading on to the "Ecology of Pest Control", the sixth chapter, and "The Further Development of Research on Insect Populations", the seventh chapter.

Having completed one's reading and started to ponder,

one inevitably becomes aware of the lack of a subject index. It is true that individual ideas can be traced if one remembers a biological name, a used term or an author, but if one only has a hazy idea, for example, "that it had something to do with DDT or an insecticide". some chasing backwards and forwards is necessary.

It now remains to state an exceedingly important characteristic of this book, which is to aid in sorting out the exceedingly numerous facets of ecology. Again and again as I read and decided that some aspect was missing, such as genetics under-emphasized, I checked and decided that it was indeed raised and relegated reasonably to certain areas, and that to go further would have required a book on the principles of biology rather than the ecology of insect populations. Similarly with the influence of behaviour and physical factors on population problems to those particularly interested in such factors. As an example, there is the reference on page 24 to the inevitability of population survival due to the average prevailing consistency of locust swarm drop in favourable wet front areas. I eventually had to concede that it is (a) mentioned and (b) perhaps does not require emphasis in this book. As the authors say on page 34, "because our interest is focused on populations, we find it useful to think of demographic occurrences as primary events and those which affect or qualify as secondary events". Ecologists whose interests are otherwise will find this attitude a corrective influence.

Finally there is much to stimulate those concerned with pest control. The approach of "protective management" favoured by most ecologists as against species eradication is realistically discussed in a stimulating manner. Although a plea for future work towards this end is made, the reader is reminded of the ever present threat to such schemes which may result from unpredictable evolutionary occurrences. This appears to be a salutary warning that to proceed slowly is to proceed wisely.

The production of this book is excellent and printing errors are minimal.

F. L. WATERHOUSE

BIOLOGICAL OCEANOGRAPHY

Aspects of Marine Zoology

Edited by N. B. Marshall. (The Proceedings of a Symposium held at the Zoological Society of London on 23 and 24 March 1966. Symposia of the Zoological Society of London, No. 19.) Pp. x+270. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1967. Published for the Zoological Society of London.) 80s.; \$14.

It is to be both welcomed and expected that the advances in underwater technology that have occurred during the past decade are leading to a re-orientation of the traditional approach to the study of the organisms living in the deeper parts of the oceans. This book probably marks the beginning of a period when greater scientific effort than ever before will be devoted to the study of the biology of these organisms rather than their morphology and taxonomy.

Those who are familiar with the books by Beebe and Cousteau will have been introduced to a world where the light intensity rapidly falls with increasing depth until, at about 1,000 metres, the faint blue light from above is no longer adequate for visual purposes. C. M. H. Harrisson gives an interesting and comprehensive account of the methods used for sampling mesopelagic fish, assessing the merits of each type of gear while stressing the difficulties in obtaining a representative sample from such large volumes of water unless several methods are used. In this twilight region and below, the majority of the fish carry luminous organs of one kind or another, and the variety and function of these are reviewed by J. A. C. Nicol. As he points out, most of the specimens are dead

when they reach the surface, and consequently very little is known of the physiological mechanisms which control their function.

Although some fish may use the luminous organs as species specific and sexual recognition signals, many bathypelagic fish have macrosmatic males. Marshall suggests that in these species the nose plays an important part "in sniffing out odorous females in vast aqueous haystacks". In many cases this is combined with a well developed lateral line system which would increase the awareness of the fish to small movements in the surrounding water.

Nearer the surface, light coming from above has been shown to play an important part in controlling the vertical movement of the organisms which cause the deep or sonic scattering layers on echo sounder traces. In the two papers dealing with this topic Boden and Kampa demonstrate the strong correlation between surface irradiance and the migrations to or away from the surface, while Blaxter and Currie describe how they succeeded in forcing the scattering layer down by lowering artificial light sources into the water.

The other parameter, which fluctuates with depth and might be used by animals to regulate their vertical level, is that of the hydrostatic pressure. Sensitivity to pressure has been demonstrated in a number of shallow water species, and the mechanism used for detecting pressure changes is discussed by P. Digby.

The study of a large and complex community such as the plankton requires special methods of sampling and analysis to reveal the pattern of seasonal changes and inter-relationship of organisms in areas as large as the North Sea and the North Atlantic. R. S. Glover presents some of the results of the Continuous Plankton Survey which uses the facilities offered by commercial shipping for routine sampling of large areas of water. He stresses the necessity for estimating abundance as well as distribution in ecological analyses of this type and looks at the future developments in technology and techniques. This section is supplemented with a description of the properties of the blue carotenoid pigments which are characteristic of the neuston, a sub-division of the plankton found at the surface in tropical oceanic water.

Other articles include an account of the distribution of Pogonophora in the N. Atlantic by E. C. and A. J. Southward, a description of a deep sea squid by M. R. Clarke, and an account of the seasonal movements of sperm whales by R. Gambell.

The book provides a number of valuable and interesting articles on modern trends in biological oceanography, and with the exception of the photographs of echo traces, the illustrations are clear and easy to follow. The balance of the contents suffers from the absence of a section on underwater sounds of biological origin, which could perhaps have been remedied if the contributors had been invited from a somewhat wider circle.

DEREK A. DORSETT

LIBRARIES AND DOCUMENTATION

The Provision and Use of Library and Documentation Services

Edited by W. L. Saunders. Some Contributions from the University of Sheffield Postgraduate School of Librarianship. (International Series of Monographs in Library and Information Science, Vol. 4.) Pp. x+198. (Oxford, London and New York: Pergamon Press Ltd., 1966.) 50s. net.

Among the professions today librarians are demonstrating in the organization of their education that they are by no means unaware of the changing needs of society. The tremendous growth in education, the "information explosion", the growing acceptance of the need for higher

standards of library provision and the ever increasing amount of leisure time becoming available; all these factors underline the need for more and better qualified librarians. The growth of schools of librarianship in numbers, in size and in the influence they are having on the pattern of library education is one of the most important developments in this profession.

This book is a collection of special studies prepared as part of the requirements for the University of Sheffield's postgraduate diploma in librarianship. There are seven studies supplemented by contributions from two members of the school's staff. The title of the book and the series in which it appears do not clearly define its contents. A monograph is usually accepted as being a treatise on a particular subject whereas the contents of this book cannot really be said to be related. Nevertheless, the separate studies are valuable contributions to the literature.

The first study is Mrs Elizabeth Melrose's account of the work and life of Mr J. P. Lamb, the former Sheffield City librarian. Mr Lamb's achievements in the modern service he developed at Sheffield and his contributions to librarianship are clearly evident in this well and carefully written account.

"Trade literature: its value, organization and exploitation" is the title of the next contribution by Miss Elizabeth Smith in which she states: "There should... be a more conscious link between existing knowledge and the inventor; between industrial activity and pure research. One way in which industry plays its part in forging this link is in supplying a continuous flow of information on new products and processes in the form of 'trade literature'."

Miss Smith found little evidence of effective communication between researchers through this medium in this country, whereas abroad, universities collect trade literature to give students a balanced impression of industrial activity in relation to their own research. The standard of trade literature is improving, so with an associated improvement in the methods of collecting trade literature and retrieving required information there should be no reason to discourage the greater use Miss Smith advocates. There is, however, the question of economics, particularly for the public or university library attempting to serve a wide and disparate range of subject users. A recent survey¹ indicates that the use made of trade literature in public libraries at least might not be "economic" compared with the considerable work involved in keeping files up to date and maintaining indexes. For special libraries the value and use of trade literature cannot be questioned.

The next two studies, "A survey of the provision and use of library services in certain London prisons" by Mrs Penelope Rowlinson and Mr M. W. Moss's "Library service for undergraduates", are concerned with the library requirements of two very different sections of the community. Mrs Rowlinson has made a thorough survey of the services provided in four prison libraries, which have greatly improved since the public libraries took over responsibility for them, but as she points out, "The Prison Department is, in fact, availing itself of an excellent service at a relatively small cost to itself. It seems only reasonable to hope that the department will soon increase its grant to public libraries, so that the prison library service may become financially self supporting, instead of relying so heavily upon the generosity of the public library service". Mr Moss in his study is concerned with an aspect of university librarianship which at the time of writing had not influenced the development of British universities to any great extent. There are useful lessons to be learnt in this country from this well presented account mainly of activities in America.

The director of the Sheffield Postgraduate School of Librarianship, Mr W. L. Saunders, together with Mr E. W. Roberts and Miss Lisbeth Wickison, have presented the "Survey of borrowing from the University of Sheffield Library during one academic year". This survey report contains a considerable volume of data which have been

interpreted to reveal certain patterns of borrowing which have proved to be compatible with the results of previous similar surveys carried out at Birmingham and Leeds. The extent of "off-subject" or non-curricular borrowing is of particular interest; however, the provision of departmental libraries for some subjects, physically separate from the main library, is shown to have an inhibiting effect on undergraduate borrowing outside their own departments.

¹'A critical review of the surveys of scientists' use of libraries" by Mrs A. Stephanie Barber shows the same careful examination of her subject which occurs in all the studies in this volume. She states "...it is a pity that the data amassed...do not correlate well and therefore form no sound basis to a theory for increasing the scientist's effective use of published information". Recently a committee of the Library Association has been investigating scientific library services in this country. It has studied existing surveys and where no reports have been available has had to investigate requirements itself. It will be of particular interest in view of Mrs Barber's conclusions to see what assessment of existing and required services the committee will produce.

The last study is an evaluation of Referativnyi zhurnal: nauchnaya i tekhnicheskaya informatsiya, the Russian abstracting journal, by Mr H. Schur, a lecturer at the postgraduate school. There is an abvious need to examine this publication, and its coverage in various fields, in much greater detail than has been possible in this interesting but short report.

The value of this book lies in the quality of the individual contributions, and it deserves a place on library shelves for this reason alone. I hope we may see further collections of studies from the Sheffield School, but that they will have a closer relationship with each other to provide a treatment in depth of aspects of library and documentation services.

Derek Jones

OBITUARIES

Professor Frank Ernest Hoare

THE death of F. E. Hoare on May 25, 1967, after a short period in hospital, came as a great shock to all who knew him. The basic illness which had gradually developed had been completely unsuspected, and there had been no premonition in any decrease in his energy and cheerful enthusiasm.

He was born on June 22, 1907, at Brighton, where he attended the Municipal Secondary School. He gained scholarships to Imperial College, London, and studied under H. L. Callendar, who roused in him what was to prove a lifelong interest in heat and thermodynamics.

He joined the department of physics at University College, Exeter, in 1928, and remained there, first as assistant lecturer, and then as lecturer, until he was seconded to the Admiralty Scientific Service in 1940. His relations with Professor F. H. Newman were happy, and he enjoyed all aspects of university life and work. As in so many physics departments at that time, however, the teaching duties were onerous, and the general facilities and the financial backing for research were extremely meagre. It was then that Hoare developed his skill in designing and constructing apparatus, and acquired the do it yourself philosophy which coloured so much of his later work.

Hoare's early research at Exeter was mainly concerned with the determination of the Stefan-Boltzmann constant, using the Callendar radio-balance. With the improved techniques which he developed he finally obtained what was long accepted as the "best" of the directly determined values. In 1931 Hoare published A Textbook of Thermodynamics which, clear and unpretentious, and with a fuller than usual treatment of applications, was widely appreciated. His subsequent work was in the accurate measurement of the susceptibilities of diamagnetic salts. The analysis of the results, partly in collaboration with G. W. Brindley, at Leeds, led to comprehensive and reliable sets of values for the susceptibilities of ions with inert gas configurations in diverse surroundings. These have been widely used in testing theoretical calculations of space charge distributions in atoms and ions, and in correcting for diamagnetism in determining the magnetic moments of ions in paramagnetic salts.

In the course of his war service with the Admiralty, Hoare planned and conducted two research expeditions to Iceland, and later became deputy leader of more than a hundred naval and civilian personnel concerned with the testing and trials of newly developed weapons. His scientific and practical approach was invaluable.

In 1946, Hoare joined the department of physics at Leeds, where he was to become reader (1954) and later professor (1964). Much of the theoretical work at Leeds in the past thirty years was concerned with the interpretation of magnetic and related properties of metals and alloys on a collective electron basis. This led to an early appreciation of the need for much more extensive measurements in the low temperature range. Hoare was anxious to embark on experimental work in this field. This was the beginning of the building up at Leeds of the low temperature laboratories which were to provide basic facilities for a very wide range of research in solid state physics. The undertaking was a formidable one, for very little assistance by grants was obtainable for work in this field. A hydrogen liquefier was designed and built in the department, and later a helium liquefier-cryostat. It then became possible, through the efforts of a small group of which Hoare was a member, to buy liquid helium from a central source of supply; but it was not until 1963 that a modern hydrogen-helium liquefier could be installed in the department through grants which had at last been obtained.

Hoare took a helpful interest in all the low temperature work, but his more personal research, with a succession of colleagues and research students, was mainly on the determination of the low temperature specific heats of metals and alloys. The lattice and electronic contributions can be sorted out, and by measurements on, for example, palladium and its alloys with the neighbouring elements rhodium and silver, with one less and one more electron per atom, important information connected with the electronic energy band forms can be obtained. The determination of the specific heats over a range of temperature of a series of binary alloys was, however, a very lengthy and laborious undertaking. In this connexion an important technical advance was recently made by Hoare and his associates. A method was developed for semi-automatic recording on punched tapes which can be fed into a computer; this in turn, suitably programmed, provides a print-out of the magnitude and standard errors of the various contributions to the specific heat. By this means, most of the routine drudgery has been eliminated, and the overall time requirements have been greatly reduced. A vast wealth of information has now been obtained particularly on elements of the nickel, palladium and platinum triads and their alloys. The results, while consistent with the general present theoretical outlook, provide many challenging problems to be faced in the future development of the theory of the metallic state.

Hoare's extensive contributions in research at Leeds were not made at the expense of other university activities. He played a full part in lecture and laboratory teaching, gave valuable service on many university committees and was actively interested in general educational matters outside as well as inside the university.

E. C. STONER

University News:

Liverpool

Following the success of an experimental Board of Industrial Studies, formed to encourage collaboration between the university and industry, the university is to appoint its first permanent director of industrial studies. He will take charge of an Industrial Studies Unit concerned with two main activities: improving the relation and mutual understanding between industry and universities; and developing courses of industrial studies for undergraduate and postgraduate students to help the transition from university study to industrial employment.

Announcements

THE members of the Advisory Committee for Scientific and Technical Information for the 1967-68 session are as follows: Dr F. S. Dainton (chairman); Dr J. W. Barrett; Mr H. P. F. Swinnerton-Dyer; Dr G. M. Dyson; Mr D. J. Foskett; Professor S. Gill; Professor S. P. Hutton; Dr N. Kurti; Mr J. Leicester; Dr R. M. Lodge; Professor W. J. M. Mackenzie; and Professor G. A. Smart.

THE Deutsche Akademie der Naturforscher Leopoldina, Halle, recently elected the following new members in the sections indicated: *Mathematics*, Professor W. Olszak (Warsaw); *Chemistry*, Professor V. Bruckner (Budapest); *Physical Chemistry*, Professor A. Riad Tourky (Cairo); *Botany*, Professor I. Manton (Leeds) and Professor F. Skoog (Madison); *General Biology*, Professor E. Hadorn (Zurich); *History of Science and Medicine*, Professor J. Roger (Orleans-Tours).

DR ALAN T. WATERMAN, first director of the US National Science Foundation, has been awarded the Karl Taylor Compton Gold Medal by the American Institute of Physics.

APPLICATIONS for postdoctoral fellowships in reproductive physiology at the Harbor General Hospital (University of California, Los Angeles) are now being accepted for the year beginning July 1, 1968. Applicants should have an MD or PhD degree, and fellows supported by the US Public Health Service must be US citizens or have permanent resident status. US citizenship is not necessary for fellows supported by the Ford Foundation. Further information can be obtained from Dean L. Moyer, Department of Pathology, Harbor General Hospital, Torrance, California.

RESEARCH Fellowships in Forest Resources are awarded annually by Harvard University from the Charles Bullard Fund. These fellowships, which carry stipends of up to \$15,000, are open to men in public service, in academic careers and in private forestry. Further information can be obtained from the Committee on the Charles Bullard Fund for Forest Research, Littauer Center 119, Harvard University, Cambridge, Massachusetts.

A NEW permafrost map of Canada in colour has been published jointly by the Division of Building Research of the National Research Council of Canada, and the Geological Survey of Canada, Department of Energy, Mines and Resources. Copies of the map can be obtained at a cost of 50 c. either from the Division of Building Research National Research Council, Ottawa, or the Geological Survey of Canada, Department of Energy, Mines and Resources, 601 Booth Street, Ottawa.

THE manufacture of Dracone towed flexible barges, which are increasingly used for the transport of oil, drinking water and other cargoes, is to be transferred to the new Dunlop General Rubber Goods Division's factory at Skelmersdale, Lancashire, under exclusive licence from Dracone Development, Ltd., a subsidiary of the National Research Development Corporation. The Dunlop Dracone Consortium, until now manufacturer of the barges, has ceased to operate, but close association between Dunlop, Dracone Development, Ltd., and the National Research Development Corporation on the project will continue.

Meetings

PROCESS Instrumentation, October 9-20, Harwell (Post Graduate Education Centre, Building 455, AERE Harwell, Didcot, Berks.).

AUTUMN Metallurgical Days, October 16-19, Paris (Société Française de Métallurgie, Secrétariat, 47 rus Boissière, Paris XVI^o).

COMMISSIONING, Use and Maintenance of Reactor Instrumentation, October 23-November 3, Durley Hall, Bournemouth, and AEE, Winfrith (Harwell Post-Graduate Education Centre, Building 455, AERE, Harwell, Didcot Berks.).

DIET and the Central Nervous System, October 28, University of Aberdeen (J. L. Clapperton, Scottish Group, The Nutrition Society, Hannah Dairy Research Institute, Avr).

SIXTH International Congress of Allergology, November 5-11, Montreal (Dr S. O. Freedman, 1390 Sherbrooke Street West, Montreal 25).

MANUFACTURING and Processing in the Cosmetic Industry, November 13-15, Learnington Spa (Dr J. J. Mausner, Society of Cosmetic Chemists of Great Britain, 56 Kingsway, London, WC2).

THERMAL Conductivity, November 13-15, National Bureau of Standards, Gaithersburg, Maryland (D. R. Flynn, Building 226, National Bureau of Standards, Washington, DC).

DEVELOPMENT of Safer and More Effective Drugs, November 26-28, Washington, DC (Samuel W. Goldstein, Academy of Pharmaceutical Sciences, 2215 Constitution Avenue Northwest, Washington, DC).

BIOMATHEMATICS and Computer Science in the Life Sciences, March 14-16, 1968, Houston (Office of the Dean, The University of Texas Graduate School of Biomedical Sciences at Houston, Division of Continuing Education, P.O. Box 20367, Houston, Texas).

ERRATUM. In the communication "Effect of Previous Injection of Homologous Embryonic Tissue on the Growth of Certain Transplantable Mouse Tumours", by G. A. H. Buttle and Ann Frayn (Nature, 215, 1495; 1967), the third paragraph on p. 1496 should begin "The imferon (iron dextran) induced sarcoma² was found to be very sensitive to previous injection of embryonic tissue". The second line of the caption to Table 1 should refer to embryonic tissue suspension from B.S.V.S. mice. The data in Table 3 should refer to adult and foetal tissue, not maternal and foetal tissue. The twelfth line of the third paragraph on p. 1497 should begin a new paragraph: "If the Crocker tumour is used in place of the imferon induced sarcoma . . .". The first line of the last paragraph should read "The growth of tumours induced by 20-methyl cholanthrene".

Correspondence

Towards a Broader Curriculum

Sir.,—I read your report "Towards a Broader Curriculum" (Nature, 215, 1329; 1967) with the greatest interest. You should, however, realize that in one sizable part of Britain—Scotland—the sixth form curriculum is broader than in England and, at least in the four older Scottish universities, it is usual to spend four years over an honours degree. I write to suggest that it might be worth while for educationists concerned with the transition from school to university to take a good hard look at the system in Scotland which, after all, produces a significant number of graduates.

Yours faithfully,

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, October 9

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING ROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Disussion Meeting on "C.E.I. Examination Requirements—a Progress Report".

SOCIETY OF INSTRUMENT TECHNOLOGY (at the Royal Institution, 21 Albenarie Street, London, W1), at 6 p.m.—Sir Henry Jones, K.B.E.: "Sources and Uses of Energy" (Thomson Lecture).

Monday, October 9-Thursday, October 12

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2)—Conference on "The Economics of the Reliability of Supply—a Comparison of Standards Adopted in Various Countries".

Tuesday, October 10

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at 14 Belgrave Square, London, SW1), at 10.30 a.m.—Meeting on "The Production of Fish".

ZOCLOGICAL SOCIETY OF LONDON (at the Zoclogical Gardens, Regent's Park, London, NW1), at 5 p.m.—Scientific Papers.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr E. Eastwood, C.B.E.: "Control Theory and the Engineer" (Chairman's Inaugural Address).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 5.30 p.m.— Professor E. R. Laithwaite: "Making the Best of a Bad Job—What Engineering Is". (Lecture for Sixth Form Boys and Grits from Schools in London and the Home Counties. To be repeated on October 11, 17 and 18.)

UNIVERSITY OF LONDON (at Imperial College, Exhibition Road, London, SW7), at 5.30 p.m.—Professor L. A. E. Carleson (University of Uppsala): "Survey Type". (First of three Special University Lectures in Mathematics. Further lectures on October 11 and 12.)*

Institution of Mechanical Engineers, Automobile Division (at Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Annual Meeting. 30 p.m.—Mr C. H. Bradbury: "A Saga of Sound and Vibration" (Chair-6.30 p.m.—Mr C man's Address).

Wednesday, October 11

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E./
I.E.E. MEDICAL AND BIOLOGICAL ELECTRONICS GROUP (at the Middlesex
Hospital Medical School, Cleveland Street, London, W1), at 2.30 p.m.—
Symposium on "Ultrasonics and Medicine".

PLASTICS INSTITUTE, POLYMER PROPERTIES DISCUSSION CIRCLE (at 11 Hobart Place, London, SW1), at 2.30 p.m.—Meeting on "Energy Requirement in Plastics Processing".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, WC1), at 5 p.m.—Dr R. M. Loynes: "On the Concept of the Spectrum for Non-Stationary Processes".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—NUTRITION PANEL (at 14 Belgrave Square, London, SW1), at 6.15 p.m.—Dr A. Dawson: "Disaccharide Intolerance".

SOCIETY OF ENVIRONMENTAL ENGINEERS (at the Euston Tavern, 73 Euston Road, London, NW1), at 6.30 p.m.—Mr G. Hooper: "Desiceants and Desiceators".

BRITISH SOCIETY FOR THE HISTORY OF PHARMACY (at the Pharmaceutical Society of Great Britain, 17 Bloomsbury Square, London, WC1), at 7 p.m.

—Dr Marie Boas Hall: "Apothecaries and Chemists in the Seventeenth —Dr Mari Century".

Thursday, October 12

CHEMICAL SOCIETY (at the Middlesex Hospital Medical School, Cleveland Street, London, W1), at 2 p.m.—Symposium on "Aspects of Organic Reactions Mechanisms".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, SW1), at 2,30 p.m.—Informal Discussion on "Estuarial Barrages in Relation to Water Resources Development". Mr S. E. H. Ford: Dee; Mr G. C. Marshall: Morecambe; Mr Ritchie M. Campbell: Solway.

INSTITUTE OF PETROLEUM, ECONOMICS AND OPERATIONS GROUP (at 61 New Cavendish Street, London, W1), at 5.30 p.m.—Mr K. Knowles: "Seasonal Variations in Demand".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Discussion meeting on "The Influence of Changes in School Curricula on the Intake of Engineering Courses", opened by Mr G. B.

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 5.30 p.m.—Sir Lawrence Bragg, F.R.S.: "Electricity and Magnetism" (Civil Service Lecture).

Friday, October 13

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 2.30 p.m.—Colloquium on "Recent Advances in Measurement Circuits Using Semiconductor Devices".

Institution of Electrical Engineers (at Savoy Place, London, WC2), at 5.30 p.m.—Mr A. E. Brewster, Mr G. M. Gardiner and Mr R. J. Hodges: "Ultra-High-Speed Magnetic Printing and Display Systems".

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the I.E.R.E., at the Middlesex Hospital Medical School, Cleveland Street, London, W1), at 5.30 p.m.—Symposium on "The Ariel III Satellite".

Saturday, October 14

JOINT BIOLOGY COMMITTEE (in the William Beveridge Hall, University of London, Senate House, Malet Street, London, WC1)—Conference on "Some Aspects of Plant Physiology".

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, SE23), at 3.30 p.m.—Mr Michael R. K. Lambert: "Moroccan Summer—an Expedition to the High Atlas and Sahara".*

Monday, October 16

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 1.15 p.m.-Professor George Porter, F.R.S.: "The House of Michael Faraday".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, SW1), at 5 p.m.—Mr N. W. Hussey: "Prospects for Integrated Control in Protected Cultivation".

ROYAL INSTRUCTION (at 21 Albemarle Street, London, W1), at 5 p.m. – Professor G. Wilse Robinson: "Why is Oxygen Blue?" (Bourke Lecture).

BRITISH COAL UTILISATION RESEARCH ASSOCIATION (at the Institution of Civil Engineers, Great George Street, London, SW1), at 5.30 p.m.—Mr Harry Perry: "Current Coal Utilisation Research in the U.S.A." (Sixteenth Coal Science Lecture).

INSTITUTION OF MECHANICAL ENGINEERS, INTERNAL COMBUSTION ENGINES GROUP (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "North Sea Gas—Internal Combustion Engines".

APPOINTMENTS VACANT

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER and an ASSISTANT LECTURER (with an interest in fluid merhanics) in the DEPARTMENT OF CIVIL ENGINEERING—The Staff Officer (586)(2). The University of Aston in Birmingham, Gosta Green, Birmingham, 4 (October 11).

LECTURER or ASSISTANT LECTURER, Grade B (preferably with an interest in the taxonomy and morphology of micro-organisms) in Microbiology, to the control of control of the control of con

RESEARCH ASSISTANT (with a good honours degree in mechanical engineering or physics) IN THE DEPARTMENT OF MECHANICAL ENGINEERING, to work on exciting new developments in the prediction of the fatigue life of metals—The Secretary, University College London, Gower Street, London, WC1

RESEARCH DEMONSTRATOR IN THE DEPARTMENT OF PHYSIOLOGY to work in the field of placental transfer and foetal nutrition of sheep—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire, quoting Ref. M.17.

RESEARCH STUDENT IN CHEMISTRY to work with the Head of the Department, Professor G. H. Williams, in the field of free radical chemistry—The Secretary, Bedford College (University of London), Regent's Park, London,

NWI.

SENIOR TECHNICIAN OF TECHNICIAN (preferably with experience with an electron microscope or in cell biology) to assist in research on fine structure and function of plant cells—Mr A. D. Greenwood, Botany Department, Imperial College of Science and Technology, London, SW7.

TECHNICIAN IN THE PHYSICAL METHODS SECTION OF THE DEPARTMENT OF CHEMISTRY to operate spectroscopic instruments—The Deputy Secretary, The University, Southampton.

TEMPORARY LECTURER/ASSISTANT LECTURER IN SOCIOLOGY—The Registrar, The University, Keele, Staffordshire.

REPORTS and other PUBLICATIONS

NATURE

Editorial and Publishing Offices: MACMILLAN (JOURNALS) LIMITED, 4 LITTLE ESSEX STREET, LONDON, W.C.2-Telephone Number: 01-836 6633. Telegrams: Phusis London, W.C.2.

Subscription Department: MACMILLAN (JOURNALS) LIMITED, BRUNEL ROAD, BASINGSTOKE, HAMPSHIRE Telephone Number: Basingstoke 5431

Advertisements only should be addressed to: T. G. SCOTT & SON, LIMITED, 1 CLEMENTS INN, LONDON, W.C.2.

Telephone Number: 01-405 4743

HOW TO BUY NATURE Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one or two copies of NATURE each week is:

YEAR 1967

*12 MONTHS (52 issues and 4 indexes) Great Britain and Eire.....£14.0.0 each

United States of America. (by air freight). \$44 each
Canada. (by air freight). \$47.80 each
Elsewhere overseas by surface mail. £13.15.0 each

YEAR 1968

*12 MONTHS (52 issues and 4 indexes)

.....£14.0.0 each Great Britain and Eire..... United States of America.....(by air freight)

(Charge for delivery by air mail on application.) *Shorter periods pro rata. (Minimum three months.)

MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

12 MONTHS (52 issues and 4 indexes)

Number of	G.B. &	U.S.A.	Elsewhere	
Copies	Eire	(by air	(surface mail)	
3–5 6–11 12 or more	Each £13.10.0 £12.15.0 £12.0,0	Each \$42 \$40 \$38	Each \$46.00 \$43.60 \$41.70	Each £13.10.0 £12.15.0 £12.0.0

12 MONTHS (52 issues and 4 indexes)

G.B. & Eire	U.S.A. (by air	Elsewhere (surface mail)	
Each £13.10.0 £12.15.0	Each: \$46.50 \$44.50	Each \$50.50 \$48.30	Each £13.10.0 £12,15.0 £12.0.0
	Eire Each £13.10.0	Eire (by air Each Each; £13.10.0 \$46.50 £12.15.0 \$44.50	Eire (by air freight) Each Each Each £13.10.0 \$46.50 \$50.50 £12.15.0 \$44.50 \$48.30

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

Any 1968 portion of subscriptions now ordered will be charged at the 1968 price.

The Real Reason for the Brain Drain

WITH all the talk there has been in the past three years about the brain drain and the causes of it, it would have been unreasonable to expect that the Working Group on Migration of the Committee on Manpower Resources under Dr F. E. Jones would have been able to suggest a dramatic remedy for the continuing loss of scientists and engineers from Britain. It is, however, a considerable benefit that the committee has lent its authority to the abolition of several fairy stories about this social phenomenon. It is especially welcome that the committee has given as the principal reason for migration the likelihood that British engineers and scientists leave for the United States because American employers make them better offers. This simple truth has been apparent for several years, though it has often been concealed by the tendency of departing scientists to say that they have been won over not so much by money as by what are called "facilities"-gas chromatography equipment and the like. The report of the working group now published emphasizes that salaries are in practice important—young men starting their careers in the United States can hope to be paid three times as much as their counterparts in Britain if they choose to work in industry. Later on, American universities are able to win away the more distinguished academics by doubling British academic salaries in many cases. The working group would have been able to rub this point in more strongly if it had been able to devise some means of making an accurate comparison between the cost of living in Britain and in the United States—the chances are that those who stay at home are inclined to exaggerate the cost of living in the United States.

In the circumstances, it may well be that the most surprising feature of the brain drain is that substantial numbers of those qualifying as scientists and engineers still elect to remain in Britain. The figures which the Jones committee has been able to assemble are nevertheless enough to justify much of the alarm there has been about the brain drain. Since the beginning of the sixties, the number of qualified people leaving the United Kingdom for at least one year has more than doubled; in 1966, 6,200 people left the country. Engineers and technologists are now more than ever the dominant component of the brain drain and the 4,200 of them who left in 1966 accounted for no less than 42 per cent of the new supply of engineers and technologists three years before. By comparison with the rapid acceleration of the emigration of engineers and technologists in the past five years, the emigration of scientists remains constant at 22-23 per cent of the annual supply three years earlier. It is only fair to add that North America takes only about half of those who emigrate each year, although it does appear that the North American demand for scientists and engineers is increasing more rapidly than that of any other region. It is also fair to acknowledge that the emigration from the United Kingdom is offset to a large extent by the movement of people in the opposite direction. As recently as 1961, indeed, it seems that emigration and immigration were substantially in balance, but this has only heightened the extent to which the ebb and flow of qualified people has been thrown out of balance in the past few years by the rapid increase in emigration offset by a substantially stagnant rate of immigration. The working group has estimated that emigrants outnumbered immigrants by 2,700 in 1966. There is nothing in the committee's report to suggest that there is any sign of slackening in this loss of skilled people from the United Kingdom.

The same points are established by the working group in several different ways. For one thing the working group has convinced itself that industry in the United States offers posts of responsibility to young engineers and scientists at an earlier age than is customary in Britain. Then taxation seems to play a part—though not a direct part—in making life in Britain less attractive for young ambitious people. According to the calculations in the committee's report, only one engineer in 200 is able to earn a net salary of £5,000 a year in the United Kingdom, and he is likely to be in his mid-forties by the time he reaches that position. In the United States, by contrast, the chance that engineers will reach that happy condition is much more like one in four. Although Mr. Wedgwood Benn quite properly went out of his way to say, when the Jones report was published, that there is no case for altering British tax laws so as to decelerate the brain drain, there is probably a strong case for believing that the British system of taxation will be something to be reckoned with by those who make a practice of counting emigrants for as long as it persists. As the committee points out, for example, high marginal rates of tax make it expensive for employers to reward technical people as well as they would like to. The trouble here is that the pinprick of taxation is only one of several reasons why it is easier for prosperous countries like the United States to compete successfully with the less prosperous countries of western Europe for the services of the most talented people. Ironically, of course, the result is often to drain away the talent on which prosperity depends.

It is, of course, a great improvement that the reality of all this has at last been recognized and the Jones committee might have earned its keep if it had done no But it has also made a number of practical recommendations, some valuable and some which would increase the spate of public and somewhat idealistic speech-making which there has been about the brain drain. It is, however, entirely admirable that the committee has rejected proposals whose effect would be to restrict the right of technical people to emigrate if they choose. Even a curb on foreign advertising for technical people is turned down, no doubt to the chagrin of some of those in official circles who have from time to time advocated some course Instead, the committee has plumped for positive solutions and has in particular taken the view that the best way of preventing the brain drain is to arrange that Britain should become more prosperous than it is. It is not surprising, therefore, that a good deal of what it has to recommend consists of policy making in the broadest sense—it wants to be assured that expenditure on research and development will be used as efficiently as possible for increasing the national product and it wants better planning between Government and industry on the conduct of research, more mobility for people (which will be a familiar cry to the Fulton Commission on the Civil Service) and better management in industry. All this is sensible enough and possible as well.

The committee's recommendations on the way in which individual scientists and engineers are dealt with in industry are in many ways the most controversial. To many outside the technical professions, they will seem like a charter for the aggrandizement of scientists, but they are no less sensible on that account. The committee would like to see a "national policy" for paying good young engineers, technologists and scientists more money, and it has done a valuable service by pointing out that the way in which civil service scales of pay are at present linked to what is paid elsewhere by a doctrine of "fair comparisons" serves as a means of preventing industry from gaining a permanent advantage. But this, of course, is only half the tale. The committee would have done well

to preach a little more at industry, for it remains a puzzling phenomenon that even progressive industrial undertakings will often fail to recognize that good men are capital assets to a company and that the commercial price that should be put on them is often much higher than the rate at which it is possible to hire them on what is clearly a buyer's market. And it would have helped if the committee had done more to suggest how it would be possible to implement the recommendation that industry should give technical people greater "opportunities for promotion to the boards of companies". Would it not perhaps be a step in this direction if academic courses at the universities were more often accompanied by practical training in industrial techniques of various kinds?

The committee also indulges in the now conventional opinion that universities should "reverse the current tendency to train scientists towards academic achievement as an end in itself". This seems to be a continuing misconception about the character of scientific training and its relationship with the contributions which the people trained are likely to make to industry. It is odd that a committee which has correctly diagnosed the reasons why graduates in technical subjects emigrate has not of its own accord worked out that much of the unwillingness of young people to enter industry may be explained in the same way. Indeed, the chances are that the impoverishment of scientific and technical careers in industry contributes in an important way to the drift away from science in the schools. The danger is that by trying to impose an artificially practical pattern on scientific education in the universities, the committee and those in even more influential positions who adhere to the same view will make things worse and not better. To say this, of course, does not imply that there is no room for closer relations between the universities and industry-indeed the committee is right to urge that deliberate steps should be taken in that direction, and there is every likelihood that even modest numbers of research contracts placed in university laboratories would help to stimulate not merely an awareness of industry but a better pattern for university education as a whole. This, fortunately, is something that even universities now appreciate.

How Foundations Should Spend Money

THE Wolfson Foundation is planning to break new ground with its scheme to encourage projects in British universities directed at goals which are somehow linked with the prosperity of British industry. It is, of course, understandable that in the years after the war, British foundations should have been most of all concerned to help remedy the shortage of facilities and people for academic research. It is equally plain, now when the lesson is beginning to sink home that Britain is now most badly provided with facilities in science and technology, that the foundations should take a lead in the encouragement of more practical programmes of

research. In this, of course, there are some precedents to help. In the United States, for example, the Rockefeller Foundation has done wonders in the past decade by its encouragement of schemes for the improvement of agriculture. What the Wolfson Foundation is planning, however, is at once more imaginative and more difficult. In the past the foundations have been proud, and rightly proud, of their freedom to make grants for projects with much more freedom from practical considerations than other grant-giving organizations can aspire to. It will be interesting to see how successfully the Wolfson Foundation will be able to single out

deserving projects when the criteria of success are linked not with the promise of academic gain but, rather, with the promise of economic benefits of various kinds. One obvious difficulty is that the foundation will find itself having to encourage extremely speculative ventures. If the object, for example, is to improve the productivity of the electronics industry, there will be no point in looking for mechanical inventions which will actually improve the production process, for industry is

likely to have thought of projects like that off its own bat. By the same token, the foundation is unlikely to find much scope for its activities in projects of the kind which the Government establishments at present carry out. But this, however, seems to be fully appreciated. The object is somehow to devise new ways in which universities at present too detached from the problems of the economy and industry can make useful contributions.

Changes for Cambridge?

The University of Cambridge publishes this week its answer to the Franks Commission Report. In fact the comparison is unfair, because the committee under Dr W. W. Grave considered only the administrative functions of the university, and excluded consideration of admission procedures, the relationship between the university and the colleges, and the like, which took the Franks Commission so long to work out. Dr Grave, Master of Fitzwilliam, has taken only a year to produce the report, advised by a committee of three, Mr J. S. Boys-Smith, Sir Frank Lee and Lord Butler.

The report recommends a number of administrative adjustments. The Senate of the university, to which all holders of the MA belong, would give up some of its powers to the Regent House, the body representing the resident teaching and administrative members of the Senate. The Senate should retain only the power to elect the chancellor of the university and the high steward. The Regent House, which should consist of all teaching members of the university (and not only those already members of the Senate) should be responsible for electing the vicechancellor, conferring degrees, approving new courses leading to degrees, and deciding broad questions of building policy. At present, though, Regent House is often asked to determine detailed implementation of policy, and the report recommends that these detailed decisions be transferred to central bodies such as the Council of the Senate. The central bodies themselves should also be reorganized. At present there are three —the Council of the Senate, the General Board of the Faculties and the Financial Board; the report recommends that the Council of the Senate should become the supreme body, and that the other two should rank as committees of the Council. This change, the committee hopes, will reduce the continuous reference back that exists between the three administrative offices. The new council would consist of the chancellor, vicechancellor, two members from among the heads of colleges, two professors or readers and twelve members of the Regent House.

The report also seeks to make it harder for the Regent House to block new legislation. Requests for ballots should need at least twenty signatures, and proposals should not be rejected unless objectors are in a majority and number more than 100. In proposing changes in the tenure of the vice-chancellorship, the committee has reached a compromise between the two year period now in operation and the four year term which the University of Oxford has adopted. Rather half-heartedly, it recommends a term of three years. The election of proctors should not be changed, but women should be eligible. The report also recommends,

perhaps with the Prince of Wales in mind, that a press officer for the university should be appointed.

. . . and for Oxford

from our Oxford Correspondent

THE University of Oxford is ringing in the academic year with some long awaited changes. For the past three terms Congregation, the assembly of the senior members of the university, has been debating fourteen new statutes reframing the administration of the university according to the proposals of the Franks Commission. The statutes have now been published, and will become effective subject to the formal approval of the Queen in Council. From 1969 onwards, the vicechancellor, who will no longer have to be the head of a college but only a senior member of the university. will be elected by Congregation on the nomination of a committee. Since 1957 the term of office of the vicechancellor has been fixed at two years, a period too short for him to do much more than learn his duties, which include the chairmanship of all the more important committees of the university and the representation of the university to outside bodies. Under the new statutes vice-chancellors will remain in office for four years; the term of the present vice-chancellor will be extended until the election of his successor. The Hebdomadal Council, whose functions are comparable with those of a government cabinet, is to be made formally responsible for the administration of the university, and the administrative services which execute its decisions are to be unified under the registrar.

The new statutes differ from the proposals of the Franks Commission over the question of the composition of the General Board, the concern of which is with matters academic rather than administrative. At present the board consists of the vice-chancellor. certain other university officials, and one representative from each of the sixteen faculties. The Franks Commission had proposed that there be only five faculties, each with two members of the board, and that many of the present faculties be reduced to sub-faculties. A year ago, Congregation approved the scheme in principle, by 114 votes to 112. The Hebdomadal Council and the General Board itself, however, opposed the proposal "because it seemed to them that the new faculty boards would have no clear function to perform, and that the new sub-faculty boards (up to forty in number) would fragment academic administration too greatly". Congregation was therefore advised to reject the statute, and the constitution of the General Board will remain the same, with the important exception that no longer will all the faculties be represented. Instead, six board members will be chosen by Congregation from the nine arts faculties, and six from the seven scientific faculties.

No Swan Song Yet

To read the annual report of the Atomic Energy Authority is to forget that the organization is going through a crisis. There is, it is true, a little retrospective nostalgia about the early days at Calder Hall, now ten years away, but the report barely mentions the reduction in expenditure at Culham, or Lord Penney's imminent retirement and the urgent need for a successor. The report gives the impression that the authority will go on for ever, occasionally annexing new fields of research, but basically unchanged. Perhaps it will, but to outsiders this is beginning to look increasingly unlikely.

It has been another year of success for the authority, although expenditure on nuclear research and development was held at the 1965-6 figure of £38.5 million. Capital expenditure in this area did increase, from £8.5 to £11 million, and research expenditure in nonnuclear fields was up to £772,000, most of it spent on desalination. The trading fund, which covers sale of isotopes, electricity and nuclear fuel services, made a profit of £3.3 million, £0.8 million up on last year, despite a 25 per cent reduction in the sale of fuel because of the reduced requirements of the Central Electricity Generating Board for initial charging for new magnox stations. The resources of the trading fund are to be used to pay for the re-activation of the Capenhurst fuel enrichment factory. The changes at Capenhurst, the report reveals, involve the complete reconstruction of the larger process units of the plant, and the enlarged factory will supply enriched uranium for the first three advanced gas cooled reactors,

Dungeness B, Hinkley point B and Hunterston B.

The expenditure of the authority has declined this year, from £78.8 million to £71.5 million, and receipts, which include payments from the Ministry of Technology for military purposes, have increased by £4 million; as a result, the net expenditure is given as £17 million against £28 million last year. The development of reactor systems has of course continued, and the prototype fast reactor at Dounreay made progress. Contracts have now been placed for about half the work on the station, and the fuel specifications will be completed soon. An improved sub-assembly has been examined in some detail, and design detail of other materials has continued. The steam generating heavy water reactor at Winfrith was completed, and confirmed that this type of reactor can be built comparatively quickly, because all the principal components can be shopfabricated.

Getting round GATT

Mr Wilson's latest device for cutting the British import bill has been constructed with considerable tactical skill. GATT, the General Agreement on Tariffs and Trade, frowns on most easy ways of aiding the balance of payments—import surcharges, or direct subsidies to home producers—and import restrictions invite retaliation from other countries. The British Government is now proposing to establish a new indus-

try in Britain by allowing aluminium companies to negotiate special prices for the electricity which they use to smelt aluminium. The smelters will pay the generating boards a sum equal to the capital cost of the power needed, and will then buy the electricity at near cost price. Because of the advantages of building big, and the fact that no smelting plant so far contemplated could use the entire output of a large station, it is likely that the aluminium companies would take a proportion of the output of a 1,200 MW nuclear station, perhaps as much as 300 MW. Electricity could then be supplied to the smelters at prices as low as 0.5d. a unit if they were prepared to build plants next door to power stations. Transmission costs would increase this slightly if the power station and smelting plant were not next door to each other.

The financial arrangements for the deal are confused. In addition to the low cost power, investment grants at the rate of 45 per cent will be given for the smelter, but the aluminium companies say that they will also need investment grants for their share of the capital cost of the power station if they are to compete with smelters in the USA, Labrador and Newfoundland, where power costs are around 0.25d. per unit. The Ministry of Power has different ideas; it confirmed this week that investment grants would be available only for the smelting plant and not for the power station.

But if aluminium is to have these advantages, why should not other industries also jump on the bandwagon? This has been the perfectly understandable response from a number of industries. The Prime Minister made clear that the favourable terms would only be available in development areas and when the investment could be seen to aid the balance of payments. There is another important proviso, however; the arrangements will not be available to existing companies for existing operations. Only if they are prepared to sanction large expansion in their activities, or a completely new industry, and offer savings to the balance of payments (£30 million is the estimate for the aluminium companies), would the arrangements be negotiable. In other words, existing businesses using large quantities of electricity will have to put up very convincing cases—and a huge investment, of the order of £1 million for every 10 MW of powerbefore they are likely to get anywhere.

power for chlorine manufacture may be the best prospect outside the aluminium companies. Other possibilities include British Petroleum, with its new petrochemical interests, and possibly Courtaulds. The other processes which use electricity intensively—magnesium, sodium, potassium and calcium production, for instance, are probably not large enough to justify special arrangements. The British Steel Corporation produces more than 3 million metric tons of steel annually by the electric furnace method—almost 14 per cent of the total output—but since production is already in progress, and expanding, it is unlikely that the BSC could legitimately claim cheap power, even as a means of achieving its cherished aim of cutting steel prices. The first plan, put up by Rio Tinto Zine, is still the simplest;

The bid by Imperial Chemical Industries for cheap

RTZ would share a 1,200 MW station with the Atomic Energy Authority. The AEA share of the power would be used to run the uranium enrichment plant at Capenhurst, expanded—hopefully—to supply uranium to the Common Market countries, if Britain gets in.

New Look for Gas

It would have been difficult to predict ten years ago the speed with which the energy pattern of the United Kingdom has been transformed by the discovery of natural gas. As Sir Henry Jones, chairman of the Gas Council, explained in his Thomson Lecture to the Society of Instrument Technology on October 9, the picture changed on August 14, 1959, when the Slochteren field, containing at least 60×10^{12} cubic feet of gas, was discovered off the Dutch coast. It was not until 1964 that gas was found in the North Sea, and now Sir Henry puts the potential supplies at 3,000 million cubic feet a day for the next 20 to 30 years—as usual, he is more optimistic than the Ministry of Power, which believes that the fields can bring in 2,000 million c.f.p.d.

So far, all Sir Henry's optimism has been justified, but he is determined to preserve a sense of proportion. Over a full year, the ministry prediction is equivalent to 25 million tons of coal: perhaps, if this rate could be doubled within ten years, the coal equivalent would be 50 million tons a year. "Natural gas will provide a most valuable addition to our country's resources, but it will not replace all the coal used nor will it render imports of oil unnecessary." Sir Henry emphasized the Gas Council view that supplies must be built up quickly—"a high speed build-up seems to me to be absolutely essential." But negotiations on terms and conditions of gas supply had not been easy, he admitted, and expressed the hope that purchase terms could be settled fairly quickly.

Unlike his opposite number at the National Coal Board, Lord Robens, Sir Henry believes in nuclear power stations. Fission, or possible fusion reactions, will, he believes, soon be able to supply the cheapest heat available for very large installations working at high load factor, and the capital cost of nuclear stations will fall. But, as a reassurance to those in the gas, coal and petroleum industries, Sir Henry quoted the laws of thermodynamics. Fuel used in heat engines to generate electricity will, he thinks, always exceed the heat equivalent of the electricity produced, and the cost of electricity transmission, on a heat equivalent basis, will be greater than that for coal, oil or gas. For the provision of heat, he said, fuel burned at the point of use is likely to remain more economic for very many purposes. With that the coal, oil and gas industries will have to be satisfied.

Expanding Services

THE Post Office is undergoing a considerable reorganization in an endeavour to become a more forward-looking and efficient public service industry. The Government decided in August 1966 to convert the GPO from a civil service department to a public corporation, and the newly published report and accounts for 1966–67 (HMSO, 14s.) gives details of the form it will take, provided the requisite legislation is passed by Parliament. The new corporation, known as the Post Office, will take over in 1969, with responsibility for all activities of the present GPO except the savings department. Total assets, numbers of staff employed and plans for capital investment will put the Post Office among the ten largest industrial concerns in the world.

Activities will be divided into the two categories of Post and Telecommunications and, unless savings

can be made by particular co-ordination in some places, they will be run as separate services. Enquiries have been made into ways of raising profitability and productivity, by McKinseys Inc., in the Post section, and by the Organization and Efficiency Branch of the Inland Telecommunications Department in their own field. Recommendations are already being put into effect, and the saving of £500,000 a year in telecommunications is only a beginning.

Overall profit rose by £4 million to £44.3 million. of which £6.6 million came from the post services Higher charges accounted for most of the increased income of £21.8 million in the postal section, bringing the total income here to £340.6 million. Three-quarters of the increased expenditure went on pay awards, but manpower productivity rose by more than I per cent Mechanization is being introduced wherever possible. in the handling of post, for example, so that letters and parcels are arriving faster than before. Ninetythree per cent of letters now arrive within a day of Experiments are being made into parcel delivery services with cheaper local tariffs, and minibus post services. A new look is also creeping into postmen's uniforms. Large scale investigations were made into the possibilities of a two-tier letter system for maximizing labour efficiency, when charges would be related to speed of delivery. Work on the National Giro continues, and market research has given promising results.

In the telecommunications section income rose to £441.8 million, but profit fell by £1.6 million to £37.7 747,000 new telephone connexions were made, but there is still a waiting list of 115,000. because of shortages of equipment. The numbers of local, trunk and overseas calls rose during the year, and these were dealt with more efficiently, either by operators or by automatic exchanges. Improvement of service for subscribers has been given priority, with good effect. £211.6 million of the capital expenditure of £242 million was for expansion of the telecommunications system. Manpower productivity rose by more than 8 per cent, partly because it was realized that it takes one man, not two, to install a new phone. Both Telex and Datel services have continued to expand, but during the year the overall growth rate of the telecommunications section has slowed down. This is thought to be a temporary situation, due to the squeeze, and as rapid expansion of investment is expected to be required in the near future, minimization of costs is an important aim.

The Post Office seems to be preparing to launch into profitable corporation business with a splash, but despite this healthy state, increased post office charges are likely to be introduced. The Postmaster General. the Rt. Hon. Edward Short, has explained why these increases are thought to be necessary. The sheer size of the telecommunications expansion programme will be beyond the resources of the Post Office. More money will have to be borrowed from the Exchequer. for which interest will have to be paid. The interest bill stands at present at £60 million a year, and will rise further with the increases in borrowing. To ask why the telecommunications system should be selfsupporting is to come back to the question of how the resources of the country are best allocated. For this reason the proposed price increases are being put before the Prices and Incomes Board.

Trees and incomes Doar

Even More about Torrey Canyon

THE effect of the Torrey Canyon disaster of March 18 on marine life continues to be studied by biologists. Two teams—one from the Marine Biological Association at Plymouth, and one sponsored by the Ministry of Agriculture, Fisheries and Food—have, since April, been assessing the biological damage below low tide mark in the vicinity of Porthleven and Gunwalloe. The results of their observations are published in the Underwater Association Report for 1966–67.

It is now generally accepted that detergents, highly toxic emulsifying agents, do most of the damage to marine organisms. The data in the report indicate the symptoms of infected animals, and one noticeable feature is the differential vulnerability shown by some species. Among the Decapod Crustacea, the commercially important edible crab, Cancer paganis, and the lobster, Homarus vulgaris, are relatively resistant but become sluggish when seriously affected and crabs may lose their legs. Some molluscs, including the razor shell, Ensis siliqua, are extremely vulnerable and appear to enter a narcotized state before death. Black patches develop on the epidermis of certain echinoderms in weak concentrations of detergent, and in stronger concentrations the animals quickly die and fall into gulleys between rocks. Fish were noticeably absent in areas heavily treated with detergent and very few corpses were seen. also investigated two important ha The teams habitats—rock with Laminaria forest, and clean sand. Of the two, unhealthy and dead species were more common in the sand habitat: evidence of damage in the rock habitat was only seen for a limited distance offshore and, by the beginning of June, all corpses had disappeared and only healthy ones remained in rather depleted stores stocks.

The cause of the differential vulnerability is unknown. It may be caused by differences in habitat or differences in the feeding habits of the various organisms.

Hazards below Ground

THE Federal Radiation Council in the United States has now set out to provide guidance for the control of radiation hazards in uranium mining—chiefly an enhanced risk of lung cancer. The principal cause of the increased incidence of lung cancer among uranium miners is continued exposure to the radioactive decay products of radon-22. These are polonium-218, lead-214, bismuth-214 and polonium-214. It is known that some of the radon daughters contained in the air breathed by miners are retained in the respiratory system. The development of lung cancer may follow some ten to twenty years later.

The council measures the hazard in working levels, defined as any combination of radon daughters in 1 litre of air that will result in the ultimate emission of 1·3·10⁻⁵ MeV of potential α-energy. In unventilated underground mines, the concentration of radon daughters has been found to vary from a fraction of a working level to several hundred times the level. Although some degree of risk presumably exists at all levels of exposure, maximum incidence of lung cancer occurs when the cumulative exposure exceeds 1,000 working level months (WLM), when the miners are moderate to heavy smokers, and when they have worked in mines for ten or more years.

A significant reduction in the concentration of radon daughters in the air of underground mines has been achieved since 1960. The simplest control technique is by ventilation with fresh air, although studies have been made on possible procedures that might be used to prevent the diffusion of radon from rock into mine air. Another practice is to limit a miner's occupancy time in relatively high concentrations of radon or its daughter products. Despite the healthier working conditions introduced during the past decade, the council recommends that steps to make improvements should begin immediately and made operational as soon as possible. But the council recognizes that present regulations and technology are inadequate to ensure compliance with its recommendations. It puts its trust in research, development and education of the miner.

Wider Patent Laws

DELEGATES from twenty-four countries—Argentina, Australia, Austria, Belgium, Brazil, Canada, Czechoslovakia, Denmark, France, West Germany, India, Italy, Japan, Mexico, Netherlands, Norway, Poland, South Africa, Spain, Sweden, Switzerland, UK, USA, and USSR—were meeting this week in Geneva to discuss the plan for a Patent Co-operation Treaty which has been prepared by the United International Bureaux for the Protection of Intellectual Property (BIRPI). Agreement could imply a big step forward towards a more rational patent law.

Many attempts have been made to do this. Patent Group of the Union of the Industries of the European Community has already tried to unify the patent system of the Six, but that plan has, for the time being, been shelved. The Council of Europe has the Strasbourg Convention which standardized administration procedure in making a standard application form for all countries. The big problem is, however, to obtain wider coverage for patents; as things are, applications have to be made to each country separately and this takes much time and expense and even then may not be entirely satisfactory. The meeting in Geneva was to discuss plans for an international centre for patents where a patent application would be forwarded to by a national office. The centre would distribute the patent application to any country nominated by the inventor. How much work this centre would do is one of the topics debated this week. It has been suggested that the centre should issue a report of novelty; an immediate anticipation search should be carried out by the centre or the national patent office but using the same standards, and a certificate of patentability should be issued by the centre after a patentability examination has been carried out by the centre or the national patent office. The certificate would have indicative value only and national offices would be under no obligation to recognize it. The British attitude to these and other proposals should be clarified when the report of the Banks Committee on Patent Reform is published in the middle of next year.

Facing the Food Shortage

An international seminar on Change in Agriculture is to be held in September 1968 and is being organized by the University of Reading with the co-operation

of the Rockefeller Foundation. The steering committee under Professor Bunting of Reading consists of eminent agriculturists from both sides of the Atlantic. It is drawing up a timetable for ten days of intensive and, it hopes, constructive work on improvements in agriculture. Case studies of various agricultural projects in areas of both high and low productivity will be presented, in the hope that some general principles will emerge as to how best to improve farming methods in unproductive areas. Technical knowledge is available to improve crops, in some cases to three times the present level, but the best means of applying new methods are as yet undefined. It is hoped that constructive suggestions will emerge during discussion at the seminar, which will be attended by about 150 people, including conomists, educationists, sociologists and agriculturists. The steering committee hopes that by restricting the attendance at the seminar, results will be produced. Detailed reports of the proceedings will be published.

Airlines Grounded

The latest victims of economic hardship in the United Kingdom are the airlines, whose operating figures for the first half of 1967 do not show the usual healthy upward trend. Compared with the same period in 1966, the number of passengers carried has risen by only 2·2 per cent to 5·46 million—in recent years, increases have been nearer 10 to 15 per cent a year. Although the airlines have increased their capacity by 8·6 per cent to 7,051 million seat miles, passenger miles have only increased by 5·3 per cent to 3,915 million. Freight carried has dropped by 13·5 per cent to 149,309 short tons, although total load has risen by 5·2 per cent to 523·4 million short ton miles.

The worst hit seem to have been the shorthaul services within Europe. Comparing the June 1966 and June 1967 figures, British European Airways have carried 6.6 per cent fewer passengers, and the load factor is down from 67.4 per cent to 60.1 per cent. In the same period, freight fell by 26.8 per cent and mail by 29.1 per cent. The private companies fared even worse; freight fell by 36 per cent, and mail by 60 per Although the seamen's strike in June 1966 gave the airlines extra traffic which they could not expect to maintain, the figures show that the weight of cargo carried has increased very little over the past five years. Longhaul services, fortunately, do not seem to have been as badly affected. BOAC carried 3.3 per cent more passengers, and 6.1 per cent more mail, but 10.7 per cent less freight.

The real blow to the airlines seems to have been in the holiday business. The inclusive tours to Europe expanded only modestly this year, although the annual increase has usually been between 40 and 80 per cent per year.

Since inclusive tours can be paid for in sterling, it is unlikely that the £50 currency limit can be blamed. In any case, it is the less expensive tours which have been hardest hit, which suggests that general economic conditions have dictated a holiday at home for many who might otherwise have gone abroad. Within Britain, improved rail services have affected airline traffic. With these latest statistics, it is easy to see why the Air Transport Licensing Board recently sanctioned increases in fares.

Social Science at Boston Spa

ELEVEN miles of library shelving were added to the existing twenty-five when Mr Patrick Gordon-Walker, Secretary of State for Education and Science, opened a new extension of the National Lending Library for Science and Technology at Boston Spa, Lincolnshire, on October 5. At the same time, a new service for social scientists was inaugurated. From now on the library will hold journals and periodicals devoted exclusively to the social sciences as well as those previously held in which the subject was mentioned. There are at present no plans to build up a stock of social science books but, following the report on libraries by the University Grants Committee, the future policy of the library is under discussion.

More than 500,000 requests have been dealt with in the past year, for photocopying papers, as well as borrowing books, and the stock of 650,000 volumes makes the library the largest scientific lending library in Europe. A new list has just been published of the 28,000 current periodicals that are held by the library.

Efficient use of scientific information becomes more important each year as the volume of literature increases, and the staff of the library have for several years been organizing courses of instruction in this field. The first courses, five years ago, were held for research students, but became impossibly oversubscribed. The present plan is to instruct academic staff and university librarians in the hope that they can run courses for their own students. In the meantime, the library is using modern handling techniques such as conveyor belts, and is streamlining cataloguing methods so that requests for information can be dealt with in the fastest possible way.

Foundation for Prosperity

THE Wolfson Foundation has decided in principle to set aside up to £500,000 over the next five years for agreed projects in applied science education which in the judgment of the trustees are most likely to improve the economic position of the United Kingdom and help the modernization of British industry. It is intended that universities should apply for quite substantial sums of money to carry out specific projects of this kind and it is apparently understood that the total sum now allocated is unlikely to be able to support more than half a dozen projects or so. At the same time, the trustees of the foundation are breaking new ground by their determination to seek out, by discussion with universities, proposals for projects that will qualify for In deciding where to place money, the support. foundation has apparently decided that it will give particularly favourable consideration to universities which have established in the natural course of events close relationships with local industries.

The motive behind this new development is the argument that the Government and the foundations have in the past twenty years done much to stimulate academic research and have, unwittingly, contributed in the process to the strong emphasis on academic problems now apparent in university research of various kinds. In its new work, which will consume somewhat less than half of what the foundation is likely to spend in the next five years on higher education as a whole, the Wolfson Foundation is looking for kinds of research

and development projects which are quite new, at least in British universities. It has in mind, for example, the way in which a number of universities in the United States have been able to surround themselves with research institutes with specialized interests in various kinds of industries. Among the kinds of projects it would like to encourage in Britain are, for example, schemes which might yield industrial and economic benefits by making it possible to manufacture electronic components more reliably and therefore more cheaply. No doubt it would look favourably on projects whose results might be a shortening of the time spent on developments of all kinds. But it seems also aware of the way in which the effectiveness of British industry could be enhanced by the development and introduction of schemes for training specialists of various kinds with great despatch.

More Facts about Schools

The latest Statistics of Education (HMSO, £1 7s. 6d.) are a rich lode for sociologists. As well as providing further evidence of the distaste for science in the schools, the tables provide fascinating information on the sociology of immigration. In the country as a whole, immigrant children (defined as those who were born outside the UK, or whose parents came to the UK after January 1, 1956) make up only 1.8 per cent of the school population. But there are wide variations —in the Inner London Education Authority 12·1 per cent of the pupils are immigrants, while the Welsh authorities have only 0.1 per cent, despite Tiger Bay. In the northern region, children from India and Pakistan make up the vast majority of immigrant children, 87.8 per cent between them, but in London they make up only 15.1 per cent, and West Indian children take the largest share, 46.6 per cent.

Perhaps these differences go some way towards explaining the differences in the knowledge of English among immigrant children. In London 55 per cent of the children have no problem with their English, while only 3.5 per cent have no English at all; in the north 7.1 per cent have no English, and only 44.7 per cent can claim that their English is entirely adequate.

The figures disclose a further decline in the numbers of children studying the mathematics/science subjects in the sixth form. This group accounted for 53 per cent of the maintained school sixth forms in 1963, but it was down to 47.8 per cent in 1966. The actual numbers in this option had declined from 47,140 in 1965 to 46,599 in 1966. Some educationists may see it as a comfort that the number of children in the sixth form who mix science subjects with the humanities continues to increase. This group now accounts for 12.9 per cent of the sixth form population, against 8.7 per cent four years ago; the actual numbers in this option have almost doubled since 1963.

Galapagos Preserved

WHILE the Ministry of Defence contemplates the destruction of Aldabra by an air staging post, the Galapagos Islands at least are in good hands. The Charles Darwin Foundation for the Galapagos Islands, founded in 1959, has had a research station on Santa

Cruz Island since 1961. Scientists have been carrying out ecological survey work with a view to deciding how best to preserve these islands, whose animals (most notably the finches) resembling but differing slightly from those of mainland South America made Darwin realize the full importance of geographical isolation in evolution. Many of the animals belong to a subspecies peculiar to these islands, and the marine iguana, unique in the world, is also the only sea-going lizard. The scientists are producing a plan for the conservation of this wildlife. The government of the Republic of Ecuador, which owns the islands, already gives financial support to the research station, and will shortly pass a law declaring parts of the archipelago a national park. Within these areas the wildlife will be completely preserved. There may be some careful direction of the forces of selection to protect any animals in danger from others. The seals may be culled to prevent them from harming the fish population. The flamingo, which was thought to be in danger of extinction, has been found an area where it can live, and it is now out of danger.

Marine iguanas in the Galapagos.

The national park of the Galapagos Islands could become an attraction for luxury tourism. Visitors will come on cruising ships and by air, to tour the islands by boat, under strict supervision. They will be expected to pay heavily, and help to subsidize the conservation work. Private enterprise, which is involved in the air traffic to the islands—there is already an air strip contributes to the research station. But the Darwin Foundation is still forced to appeal for money to replace the forty-year-old ex-Cornish fishing vessel, Beagle II, which has been essential to the research staff in their work on the islands. Anglia TV has made a colour film, "The Enchanted Isles", which is to have a special royal showing at the National Film Theatre on November 27, when the foundation hopes to raise £20,000 to build a ship that will stand up to the rough South American seas.

NEWS AND VIEWS

Don't Bring Back the Ether

It is probably too much to hope that the exchange of views between Professor Herbert Dingle and Professor W. H. McCrea which appears in this issue will put an end to a long-standing argument in special relativity. By now there is all too much evidence to show that issues like these have a habit of springing to life long after the stuffing seems to have been knocked out of them by the force of pure reason. It is Dingle who mentions Zeno's paradox, which shows that he too is fully aware of the pitfalls which can exist in what seem to be the most elementary kinds of arguments. But defining limits for the length of the diagonal of a square is child's play compared with the process of synchronizing clocks in special relativity, which means that nobody should be surprised or even alarmed that distinguished people occasionally pay close attention to these matters.

Dingle's criticism of special relativity is, of course, pretty radical as these thing go. He seems quite genuinely convinced that the theory of special relativity is seriously in error, and that there is a kind of conspiracy to hide from this supposedly self-evident and presumably unpalatable truth. He also considers that there has been something of a breach of professional propriety in the way in which his detailed assertion of his case against special relativity (Nature, 195, 985; 1962) provoked only a reply from Professor Max Born (Nature, 197, 1287; 1963). To many people, of course, that will seem an over-generous tribute to Dingle's case against special relativity, yet it is also true that Dingle's persistence with his argument is deserving of respect. He has been concerned not so much to twist the tail of orthodoxy as to draw attention to what he has for many years considered to be a serious defect in the accepted doctrine. McCrea's commentary on this argument will bring the controversy to an end for most people. It is earnestly to be hoped that it will also satisfy Dingle.

A part of the confusion which this controversy has occasioned arises because what may be called the Dingle contradiction is in many ways suggestive of other paradoxes in relativity—the clock paradox, for example. It is therefore important to be clear about the nature of Dingle's protest. He says, quite accurately, that Einstein's postulates in special relativity lead directly to the familiar Lorentz transformation for the co-ordinates of space and time and, in particular, to the notion that the time recorded by moving systems-clocks, for example, or radioactive atoms-appears to be dilated when matched against a stationary system for recording time. For example, short-lived mesons in the cosmic rays appear to observers on the surface of the Earth to last long enough to reach the ground. But time dilation works in both directions. From the point of view of quickly moving mesons in the cosmic rays, the lifetime of radioactive

atoms on the surface of the Earth will seem to be unnaturally prolonged.

All this is entirely consistent with that one of the twin postulates of Einstein's special theory which has it that there is no objective difference between inertial frames of reference moving relatively to each other with constant velocity. Dingle constructs an argument by which he claims to show that this reciprocity of time dilation implies a contradiction. If it implies that some clocks in motion must run slow, it also implies that the same clocks run fast compared with some stationary system. What McCrea has done is to point out that Dingle's construction is an attempt somehow to evade the awkward truth that in relativistic mechanics there are serious physical limitations of the freedom with which separate events can be synchronized in time. In other words, McCrea argues that Dingle has thrown to the winds some of the quite elementary precautions which should be taken by those who choose to venture into this important field. In the circumstances, it is no great surprise that he is able to establish a reductio ad absurdum.

McCrea has done a public service by the trouble he has taken in his demonstration of these points. The chances are that most people will be persuaded by what he has to say. It does not follow, of course, that those who, for one reason or another, find Einstein's version of the theory of special relativity unpalatable will promptly be forced to toe the conventional line. After all, there is nothing to prevent those who want to bring back the ether, or who would like the velocity of light to be otherwise than constant, from seeking other ways of saving the appearances. As the saying goes, it is a free country, and there is nothing to prevent people from tilting at windmills if they choose. It is also worth recalling that McCrea's demonstration will not put an end to discussion of that paradox which, in its most popular form, alleges that a relativistic space traveller will be found to have aged less quickly than those who have stayed at home. The point here is that the symmetry of the problem in special relativity is upset by the mere fact that the traveller is set in motion by the deliberate application of external forces.

There remain two quite serious aspects of the charges which Dingle has levelled against orthodoxy, and they also deserve an answer. The least contentious of them concerns the way in which theories of any kind can be challenged and destroyed. There is, of course, no question that a flagrant internal inconsistency is intolerable, and must be got rid of if the theory is somehow to survive. In practice, however, the special theory of relativity has been enormously successful in the past half-century, and in spirit as well as in detail has come to pervade the whole of modern

•

physics. Even though Dingle may say that an abandonment of strict relativity in the sense of Einstein's essential postulate would not necessarily imply the end of Lorentz transformations, it is exceedingly hard to believe that a postulate which seems entirely helpful in most of its applications should nevertheless lead to a real inconsistency, and it is no surprise that the resolution of the paradox which McCrea has provided is in a sense semantic. But in circumstances like these, where a theory is lent conviction by the sheer breadth of its agreement with experiment, it would seem incumbent on those who would overthrow it to produce not merely a contradiction but a constructive alternative.

There is also the problem of whether Dingle is right in saying that there has been a breach of professional concern for professional integrity in the way in which his original assertion has not been answered in the detail which he himself considers to be necessary. This raises interesting questions about the function

of the scientific literature as a whole. It is, in particular, important to know just to what extent the profession of science should come smartly to a halt when somebody cries scandal and says that there is something wrong with the essential character of an important theory. Dingle is right to seize on the importance of propaganda. The man who first spots an inconsistency has a duty to bring it to the attention of others, if necessary with vigour. But, especially now that most people are disciples of Popper, an inconsistency is more likely to be welcomed than ignored. Science may not be conspicuously more free from selfdeception than other kinds of intellectual activity, but everybody knows that it flourishes by upsetting applecarts. If, in these circumstances, an allegation of scandal should be ignored, that in itself is an entirely proper reason for asking whether the allegation can be well founded. It is immodest of Dingle to have plumped for the alternative supposition that the profession of science is at fault.

Can Learning be Transferred?

THE function of learning and memory would be much more easily understood if there were some chemical structure in the brain in which information could be reckoned to be stored, and this no doubt is why there has been such interest in the past two years in experiments with the object of determining whether learned behaviour can be transferred by injecting brain extracts from trained donor rats into untrained recipients. As yet, however, there is no positive evidence to suggest that transfer really occurs and there is nothing to suggest what the responsible substance might be—protein, RNA or some other. One obvious difficulty in experiments like these is that of measuring with some semblance of precision the degree to which learned behaviour can be supposed to be transferred from one animal to another by the injection of brain extract or of RNA. Another is, of course, the problem of knowing what materials are being transferred in any series of experiments.

Materials in Archaeology

from G. F. Freeguard

PRIMITIVE man was essentially unable to alter the properties of those materials which were naturally available to him, and therefore his development rested on his ability to learn by practical experience to adapt them to his requirements. Subsequently, in establishing further his mastery over his environment, man began to make new materials on an empirical basis, a process which eventually led to the manufacture of materials on a scientific basis. The annual meeting of the Materials Science Club at Banbury (September 22–23) was entitled "Materials in Archaeology" and presented an opportunity for a distinguished group of archaeologists to discuss with materials scientists the specialist knowledge which can help to unravel some of the secrets still held by the past.

The understanding of natural material may be

In the circumstances, it is no surprise that experiments so far have been in many ways conflicting. Some people claim that various learning schedules can be transferred by means of brain extracts. Others have failed to replicate these experiments. Adám and Faiszt have now (p. 198) carried out a series of experiments designed to define conditions under which training and habituation should be carried out if transfer effects are to be recognized most easily. Although the new experiments do nothing to define the chemical nature of transfer factors if these exist, there is at least the possibility that they will help to reconcile some of the conflicting reports that now appear in the literature. There is no doubt that, in this field, more accurate attention to the objectives and the significance of the experiments which are carried out cannot fail to be a boon. Whether in the long run the reality of transfer factors is established is, of course, another matter and a more problematical one.

illustrated by the building of the brochs—stone, round, tower-like structures which only occur on the northern and western coasts and islands of Scotland and which were probably built from 100 bc to ad 100. They represent the highest development ever reached in building with dry, undressed stone. The hollow wall construction which is tied together by lintels—also used extensively over the entrance of mural cells and internal wall openings—illustrates well the adaptation of a structure to the availability of materials, sandstone and metamorphic rock slabs. Observation confirms that the lintels have been able to withstand severe stresses imposed either by differential settling of the massive stone walls into which they are locked at both ends, or by imperfect horizontal alignment of the beds on which the lintels were being placed. The

strength of sandstone lies partly in the ability of the material to deform elastically: a spectacular demonstration of this can be seen in the Hunterian Museum, Glasgow, where a sandstone slab a few centimetres thick and 2.5 metres long supported at its centre sags by about 20 centimetres at its ends. Plastic deformation of poorly cemented sandstone is also possible by intergranular movement, but such deformation can only occur very slowly and must have been useful in coping with subsidence. In either case many lintels are markedly curved.

An insight into the evolution of particular technologies can be obtained from the analytical study of the composition of the artefacts. This is well illustrated in both metallurgy and ceramics. In the latter case recent X-ray diffraction studies of glasses through the ages have been applied to characterize the opacifying agents used from 1450 BC.

To quote as an example a particularly well known object, the white opaque decorations on the Portland Vase are due to Ca₂Sb₂O₇—since antimony oxide was chiefly used up to the third century AD. Tin oxide was not used until well into the Christian era and arsenic not until the eighteenth century. As an illustration of how it is sometimes necessary to modify ideas in the light of extensive analytical information, it has recently been shown that calcium fluoride is present as the agent in Chinese glass of the seventh to tenth centuries AD, whereas it had been thought for many years that such glasses were not developed until the nineteenth century.

The renovation and preservation of antique objects are of great importance if posterity is to be able to inherit the wealth that has so far been discovered. A report on the work of the British Museum in this field concluded the meeting, describing some of the solutions that have been found in the treatment of both metallic and non-metallic objects. Modern materials have a significant part to play in this work, since the aim is always to enable future workers to be able to improve on any restoration, perhaps by use of new methods and materials that may then be available.

A full account of the meeting will be published in the November edition of the *Materials Science Club Bulletin*, together with the text of the address by Professor F. C. Frank, this year's recipient of the A. A. Griffith medal. The interest generated by the meeting has resulted in the formation of a group to interchange information and give scientific assistance to field workers. Enquiries from scientists interested in participating will be forwarded to the organizers.

Improving Wheat

from a Correspondent

In recent years it has been possible to develop chromosomally deficient or aneuploid lines among the varieties of the commercial wheat of agriculture (Triticum aestivum). These lines are important, because each chromosome can be marked cytologically and followed in the generations after hybridization. It is this ability which enables the chromosomes of one variety to be replaced, one at a time, by chromosomes from another variety. In this way varieties of wheat which differ by only a single chromosome can be produced; each chromosome substitution can then be assessed for its economic benefits, and varieties better than those in current use may be produced. For this approach to

be successful, however, substitution lines must be developed on a large scale, a task beyond the scope of any one research institute, let alone any one worker.

Recently Riley and Law suggested that this difficulty could be overcome by co-ordinating European work with wheat aneuploids, and as a result a conference, supported by the Wates Foundation of the Royal Society, was held earlier this year at the Plant Breeding Institute at Cambridge to investigate the possibilities of co-ordination. During discussion it emerged that most European aneuploid material was still at an early stage, and that the first function of a co-operative would be to establish an information service by way of a newsletter through which contact could be maintained. The ultimate aim, however, should be collaboration at the work level, and a start was made on a project in which four key varieties from different parts of Europe will be involved in a reciprocal substitution The European Wheat Aneuploid Coprogramme. operative, as it will be called, includes representatives from twenty-one countries.

As well as discussing collaboration in Europe, the conference heard descriptions of work elsewhere. The history of the development of wheat cytogenetics is to a great degree the history of the development of one variety, "Chinese Spring". E. R. Sears, from the USA, who began the work with "Chinese Spring", gave a description of the development of an euploid research in his laboratory and of the range of an uploid material available in this important variety. G. Robbelen, from West Germany, gave an account of the development of a monosomic series—that is, aneuploids deficient for a single chromosome-in the variety "Wachtel" by backcrossing to "Chinese Spring"; this illuminated the great importance of maintaining precise cytological control throughout the backcross programme to avoid the possibility of "univalent shift", a process in which particular monosomics are lost. This need for precise control has also been realized in the substitution programme at Cambridge. Although monosomics can be used, the best technique employs a cytologically recognizable chromosome such as a telocentric. The requisite mono-telocentric lines could be produced relatively quickly if telecentric chromosomes from "Chinese Spring" were substituted concurrently with the development of monosomics.

Other contributions from Europe showed that a total of twenty-six varieties, representing many of the best agricultural varieties, are about to be or are being developed into monosomics. In most cases the monosomics are being developed by backcrossing the variety on to an established set of monosomics. Because this requires at least seven or eight generations of backcrossing, many of the monosomic sets are still at an early stage in their development. But the wide range of varieties being exploited in this way offers an opportunity, albeit at a later date, for an effective study of chromosomal differences at the population level.

Studying the Sea

from a Correspondent

OCEANOGRAPHERS are a versatile group. At a recent meeting at the National Institute of Oceanography, representatives of the Challenger Society and the marine laboratories discussed physical oceanography, biology, chemistry, and ship design.

J. Crease and J. C. Swallow dealt with deep currents and methods for their measurement. The use of arrays of recording instruments moored with subsurface buoyancy independent of the research vessel is now beginning to increase the amount of data which can be collected and to make possible synchronous observations of temperature and other variables. Improvements in the design of the mooring gear and in the manufacture of current meters were actively discussed. While most deep currents so far recorded are of low velocity, considerably higher velocities not caused by turbidity currents at the bottom have been seen to occur from time to time. Attempts to predict the worst possible conditions, for the information of engineers and others, must try to take into account these exceptional events.

Prediction of changes in flow and water level is a goal for oceanographers, and S. Ishiguro showed that within the relatively restricted area of the North Sea it could be done very quickly with an analogue model. This approach has already provided a fuller understanding of the combination of physical and meteorological factors which occasionally causes damaging increases in water level at vulnerable points on the English and continental coasts.

By the use of models of another sort, S. Thorpe presented the phenomena which occur between stratified fluids of different densities; of particular interest was the demonstration of internal waves breaking not at the crest but on the slope half way between trough and crest, a phenomenon which has been filmed occurring in a thermocline at sea.

For those whose fate it is to spend some part of their lives at sea it is most gratifying to find out how much research is now put into ship design. A. Silverleaf emphasized that it is only in the past twenty years that methods of measuring the waves and other factors which determine sea state have been available. As a consequence, laboratory basin experiments are now more realistic and measurements of ship behaviour at sea can be made in relation to sea conditions at the time.

It is generally assumed that fluctuations of the non-conservative constituents of sea water are due to biological activity, but C. P. Spencer showed that suspended inorganic particles are also capable of markedly affecting the quantities of dissolved nutrients. The effects of variations of temperature and salinity on the growth of crab larvae were described by J. D. Costlow. One of the more striking results was the appearance of extra larval stages not observed in natural populations when larvae were subjected to a particular temperature and salinity regime; these phenomena were shown to be under endocrine control.

The convenience of working on a large and thus relatively stable ship was stressed by J. Gilpin-Brown when he described the physiological work recently carried out by Professor Denton and himself on board RRS Discovery. Much of the work was on buoyancy mechanisms in various invertebrates and particularly the cephalopod *Spirula*. The trick of substituting ammonium for sodium ions in the body fluids to increase buoyancy, so far described only in Cranchiid squid, has now been observed in several quite different squid and in a species of crustacean. The well known subjective impression that the colour of oceanic invertebrates is related to depth was put on a more

objective basis by P. J. Herring's work on carotenoproteins and this is clearly a large field for further investigation.

The application of statistical analysis to plankton samples should not be undertaken by those who become easily depressed. M. V. Angel managed by persistence to prove that single samples of ostracods were significant in certain respects, particularly in that the order of abundance of species was consistent in ten repeated horizontal hauls made at the same depth. But the degree to which numbers can vary even from closely spaced samples was apparent from P. Foxton's series of observations on a swarm of salps. The variations were, however, caused by meaningful changes in animal density, not by sampling errors, and were correlated both with hydrological parameters and with time. To mark a particular spot in a moving water mass so that the same patch of water can be revisited over a period of time would appear to require something more effective than a parachute drogue supported by a surface buoy. The later observations were therefore treated with some reservation.

Problems of Classification

from J. G. Hawkes

To what extent and in what manner can the results of comparative studies in biochemistry, microbiology and immunology be used in classifying plants, animals and micro-organisms? To what degree should one draw conclusions on evolutionary relationships from the data obtained from these studies? These were the basic questions discussed at a symposium on chemotaxonomy and serotaxonomy, arranged by the Systematics Association at the Department of Botany, University of Birmingham, on September 15 and 16. Can one, for instance, classify a group of organisms by reference to one series of biochemical characters, such as amino-acid sequences in peptide chains, bile salt differences, anthocyanins or immunoelectrophoretic spectra? And is it permissible to infer evolutionary sequences from the degree of complexity of a series of related substances, following what appears to be a logical sequence, stage by stage, from species to species? It was felt that the answer to such questions should be a qualified negative; biochemical data can indeed be of value when placed in perspective, together with a range of other characters from the organisms studied, such as morphological and cytological ones; such data should not be used alone, nor should they be given weighting as of greater importance because they are in some way more "fundamental". Nor should surprise and disillusionment be engendered if no pattern of correlations between biochemical and other characters emerges, as, for instance, with essential oils in eucalyptus species. Such completely uncorrelated characters can be of little value in classification and, equally, one must guard against ascribing a special significance to a series of biochemical characters just because the techniques by which they are elucidated are highly difficult, tedious or ultra-sophisticated.

It is also dangerous, as emerged in the discussions, to confuse presumed evolutionary sequences with systems of classification. At times, perhaps, it is possible to infer the former from the latter, but it is always essential to understand clearly whether one

is trying to form a classification based on character similarities and correlations or trying to understand the phylogeny of a group of organisms by referring to characteristics observed only in the living representatives.

Another point discussed with some animation was whether all characters of living organisms are adaptive, even though many of them may appear not to be. Possibly the obvious phenotypic effect of a pleiotropic gene whose other, less obvious, feature is influenced by selection pressures may lead us astray at times. It was generally accepted that all variants might be adaptive, but perhaps what did not emerge too clearly was how much of this adaptive variation was based on present selection pressures, and how much was caused by pressures acting in the remote past, so setting a pattern for a particular group from which it cannot now escape.

Although one must admit that the Systematics Association had taxonomists primarily in mind when it arranged this symposium, there were few "pure" taxonomists present; and indeed most of the audience were either biochemists, microbiologists or taxonomists who had already used biochemical techniques in some way or other. No doubt, however, taxonomists and others will read the papers when they are published by the Systematics Association. The combination of papers and discussions from workers who are actively using a wide range of biochemical and serological techniques led to lively discussions and a feeling that the symposium had served a useful purpose. To me it seems that the strong links being forged between descriptive and experimental disciplines, and the wide and excitingly different biochemical and biophysical techniques now being introduced into taxonomic studies, are some of the most exciting developments in contemporary biology.

Symmetry Conserved

from our Molecular Biology Correspondent

Two articles about the sub-units of aldolase illustrate the scope for error in the evaluation of quaternary structure in enzymes. Aldolase is by no means the only case which has been the subject of this kind of ambiguity, and there are others which are still unresolved.

In this column last June two papers were briefly discussed which gave apparently conclusive evidence that mammalian aldolase consists not of four sub-units, as had initially been suggested, but of three, two of them identical. This was based on the one hand on molecular weight determinations on the intact and dissociated enzyme, and on the other on measurements of the number of catalytic sites and on hybridization studies. It now turns out that the conclusion is wrong, and that the enzyme has after all four sub-units—a result altogether more compatible with current concepts of enzyme structure.

Morse, Chan and Horecker (*Proc. US Nat. Acad. Sci.*, 58, 628; 1967) have renounced their earlier conclusion; they find four C-terminal tyrosyl groups per molecule, which indicates the presence of four chains (whereas three C-terminal and N-terminal groups have been reported at various times by several workers in the past). But there still appear to be only three active sites in the intact enzyme. Whether one site is blocked in the enzyme as isolated, or whether the attachment

of substrates at three sites inhibits the fourth, is not yet known.

The most comprehensive new evidence on the quaternary structure of aldolase comes, however, from Penhoet, Kochman, Valentine and Rutter (Biochemistry, 6, 2940; 1967). In the first place they have prepared hybrids of aldolases from different tissues by acid-dissociation and reaggregation. A mixture of the two native aldolases, A and C, yields a set of five components on hybridization, which all possess the molecular weight of intact aldolases. Whereas the parent molecules alone produce no new species on dissociation, each hybrid gives rise to a complete set of five components, made up of combinations of the two types of When these are made from equimolar sub-unit mixtures of radioactively labelled A and unlabelled C, their specific activities are in the ratio 1:0.75:0.5:0.25:0, the first and last corresponding to reconstituted A and C. It follows that the combining unit is the quarter-molecule— α in aldolase A, and γ in C—and the species formed on hybridization are α_4 (intact A), $\alpha_3\gamma$, $\alpha_2\gamma_2$, $\alpha\gamma_3$ and γ_4 (intact C). These elegant experiments are supported by electron microscopy of intact aldolases, which shows clearly the presence of four globular sub-units in intact molecules, arranged tetrahedrally.

It is interesting to examine with hindsight the published molecular weight determinations on aldolase and its sub-units. For intact aldolase, two leading laboratories produced values of 142,000 and 160,000. Whereas this discrepancy might still be regarded as marginally tolerable, the corresponding values for dissociated sub-units were 51,000 and 37,000, and this is obviously sufficient to cause an irreconcilable difference in numerology. This demonstrates that alarming differences in molecular weights are still possible, even in the most expert hands. The conditions of dissociation were different in the two studies, however, and it must be supposed that the trouble arose from incomplete dissociation, perhaps obscured by non-ideality. (Penhoet et al. have also redetermined the molecular weight of the intact enzyme by high-speed sedimentation equilibrium, and obtain values in the range 150,000-157,000.)

The results may be seen as a vindication of Kawahara and Tanford, who had the correct answer for the number of sub-units. It suggests also the advantages of dissociation by 6M guanidine hydrochloride, which Tanford and his associates have advocated, and have shown in a series of painstaking investigations (the most recent of which have just appeared in J. Amer. Chem. Soc., 89, 5023, 5030; 1967) to eliminate all measurable non-covalent interactions in all of the large number of protein chains which have been examined. Further reflexions on the experimental discrepancies concerning aldolase are to be found in the paper by Penhoet et al., and make salutary reading.

T4 Messenger RNA

from our Cell Biology Correspondent

It is well known that when T even phage infect $E.\ coli,$ some phage specific proteins are made early in the infective cycle, and as the cycle progresses the synthesis of these 'early' proteins ceases and other 'late' proteins are made. Is the mechanism regulating the cessation of 'early' protein synthesis and initiation of 'late' protein

synthesis at the level of mRNA transcription or translation? Although the answer to this question still remains obscure, some recent experiments have eliminated some of the possible mechanisms that have been

proposed in the past.

Hall et al. (1964) found that most T_2 mRNA species made early in infection (before the phage DNA replicates) are still present at late times when 'early' proteins are no longer being synthesized; this suggests regulation at the translational level. One, perhaps unlikely, possibility considered was that ribosomes by some modification are rendered incapable of binding 'early' mRNA late in infection. But as Friesen, Dale and Bode (J. Mol. Biol., 28, 413; 1967) and Baldi and Haselkorn (J. Mol. Biol., 27, 193; 1967) have shown, this is not the case. Baldi and Haselkorn report briefly that about half the radioactivity given in a pulse at late times during T_4 infection is incorporated into 'early' mRNA and this binds to ribosomes equally as well as 'early' mRNA made at early times. Friesen et al. confirm this; they found 'early' mRNA present at late times and associated with ribosomes just as it is early in infection. (The relative amounts of 'early' and 'late' mRNA at late times remain debatable; Geiduschek et al. (1966) and Kasai and Bautz (1967) claim the concentration of 'late' mRNA is 30 times that of 'early' mRNA.)

One explanation of these results is that although 'early' mRNA at late times is associated with polysomes it is not translated. The 'early' messenger mRNA itself may be altered, or part of the translating machinery other than the ribosomes may be modified; for example a new class of tRNA made at late times may read codons restricted to early mRNA as missense or nonsense. Alternatively, since Greene and Korn (J. Mol. Biol., 28, 435; 1967) have now shown early that mRNA is unstable, and if the instability of mRNA results from its participation in translation, then 'early' mRNA may be translated, albeit imperfectly, at late times and yield non-functional protein.

Greene and Korn measured the half-life of $T_A mRNA$ at all stages during infection, using C14 uracil pulse labelling and actinomycin D to stop transcription, and found both 'early' and 'late' mRNA has a half-life of 3.5 min at 37° C. Furthermore, in the presence of actinomycin the rate of protein synthesis decays with the same half-life as the mRNA. There was no evidence for stable mRNA of any sort. Earlier this year Bose and Warren (Biochem. Biophys. Res. Commun., 26, 285; 1967) had reported that $m\hat{R}\hat{N}A$ for the early enzyme deoxythymidylate synthetase is unstable. These results eliminate Edlin's (1966) suggestion that the cessation of early protein synthesis occurs by competition, for the protein synthesizing machinery, between unstable 'early' mRNA and accumulating stable 'late' mRNA.

In the light of these experiments and given that at late times new species of mRNA appear (Geiduschek et al., 1966), it seems likely that the regulatory process involves interplay between translational and transcriptional controls and there is ample evidence that in other systems the processes are interrelated.

Induction of Meiosis

from a Correspondent

New arrangements of genetic material arise from recombination and segregation of genes at meiosis.

Mitosis, however, serves to pass genetic material through many cell generations without any gene rearrangement. But what are the mechanisms which underlie the entry of a cell to the meiotic process from a previous mitotic way of life? An answer would help to explain how pairing of homologous chromosomes is brought about (for a cytogenetic approach see Riley and Chapman, *Nature*, **216**, 60; 1967), and would ultimately enable genetic analysis of higher organisms to be carried out at will in cell culture.

Yeast cells can be induced to enter meiosis and sporogenesis by transferring them from a nutritionally rich growth medium to a poor, acetate-containing, sporulation medium. Some of the biochemical and cytological changes that occur during this switch from mitosis to meiosis have been published in two papers by Croes (Planta, 76, 209 and 227; 1967). visible indications of the onset of meiosis and spore development are an increase in nuclear and cell volume and cytoplasmic vacuolation, and are apparent two hours after transfer to the sporulation medium. Simultaneously there is a sharp increase in oxygen consumption and a small increase in protein content; but these, along with the RNA content, decline as spore formation continues. This lowering of metabolic activity is surprising since the gross morphological changes of sporogenesis, such as spore wall formation, occur 14 to 20 hours after transfer. Experiments with ethionine, which blocks both meiosis and spore maturation, showed that these processes are most readily blocked if the inhibitor is added during the first two hours after transfer, while less severe inhibition results if ethionine is given 4 to 6 hours after transfer. Further experiments showed that even before transfer to the sporulation medium the cells are prepared for meiosis. Ethionine given for two hours immediately before transfer caused a 99 per cent inhibition of subsequent meiosis and sporogenesis, while mitosis in that two hours was inhibited by only 26 per cent. experiments show that the potentiality for meiosis is latent in the cell at the time of transfer and it is contact with the acetate in the sporulation medium that causes the immediate induction of meiosis.

In the second paper Croes defines some of the metabolic patterns in the cell which correlate with the ability to enter meiosis. The number of meiotic cells induced is greatest if the transfer to sporulation medium is made when the culture is passing from the log to the stationary phase of growth. This transition occurs when glucose in the growth medium is exhausted by fermentation and the accumulated ethanol is then consumed in respiration through the glyoxylate cycle. This change from fermentation to respiration accounts for the stimulation of oxygen consumption by the sporulation medium as the acetate serves as the carbon source for the glyoxylate cycle. Although these metabolic changes appear significant in triggering meiosis, they seem far removed from the meiotic process itself. There are still many unanswered questions-does this radical change in cellular metabolism affect the types of RNAs and proteins synthesized? Are there special "meiotic" proteins? How does the intracellular environment affect the behaviour of the nucleus? Finally, are there parallel changes in cells of higher organisms as they enter meiosis? A fusion of the biochemical and cytogenetic approach to meiosis should be very rewarding.

The Case Against Special Relativity

H. DINGLE

In 1962 Professor H. Dingle published an argument that the theory of special relativity is invalid. In what follows he restates his case, which is then answered by Professor W. H. McCrea.

FIVE years ago' I gave, as the culmination of several similar efforts, a simple proof that the special relativity theory was untenable. This received only one reply from an acknowledged authority, namely, Professor Max Born, who unfortunately, as he himself said2, assumed that I had expressed myself badly, and replied to what he thought I had meant to say. My assurance that what I had meant was what I had said has remained unnoticed. Nevertheless, the theory has continued to be accepted and used as though it were unquestioned.

This does not accord with the general view of the ethics of scientific practice, and, in a matter so fundamental as this, it is not only abnormal but dangerously so. It is understandable that there should be hesitation in believing that a theory so firmly established, and apparently supported by a great weight of evidence, should be disproved as simply as my letter suggested, but it is equally hard to believe that, if such a simple disproof contained a fallacy, no exposure of that fallacy (which, it may be added, there have been numerous private but unsuccessful attempts to extract from recognized authorities), should have been forthcoming. This criticism of the theory, in various forms, has been published repeatedly, during a period of almost nine years, in physical, astronomical and philosophical journals and in four books, in Britain and in America, without eliciting a single published comment. Reluctance to correct errors in such matters is not a customary feature of scientific discussion, so the natural inference is that there is here no error to correct. The balance of probabilities is therefore fairly even, but in fact that is all irrelevant because the matter must be settled not in that way but by reasoned argument. What my argument showed was that the theory was untenable because it required each of two clocks to work steadily and continuously both faster and slower than the other. I do not think it can be maintained that this is physically possible, and therefore the decision rests on the validity or otherwise of the proof that the theory does in fact require that. That is a matter of pure reason, not of opinion or probability, and therefore it admits of a conclusive solution here and now. Furthermore, the point in question is quite specific and must be dealt with specifically, not submerged in more general considerations concerning the abstract functions of scientific theories. It is of course quite permissible, and indeed inevitable if progress is to be made at all, to use theories that are unproved: it is another, and quite impermissible matter, to base experiments on a theory known to be false. To facilitate assessment of the argument I give it here in an extended form, including explicitly details which were only implicit in the former statement in Nature.

Consider the following situation.

$$egin{array}{cccc} N^ullet & & B^ullet & \longrightarrow & v \ & A^ullet & & H^ullet \end{array}$$

A and H are two relatively stationary, regularly running, clocks. B and N also are two similar relatively stationary, regularly running, clocks, moving with uniform velocity v with respect to A and H. (The distances AH and BNare independent and arbitrary.) A and H are set so that a pulse of light which leaves A when A reads T_1 , and is instantaneously reflected back from H when H reads T_2 , returns to A when A reads $T_3 = 2T_2 - T_1$. N is similarly set in relation to B. The readings of A and H are denoted by t, and those of B and N by t'.

The following are three successive events during the process.

 N^{\bullet} $B^{\bullet} t' = 0$ $A^{\bullet} t = 0$ H^{ullet}

Here B is adjacent to A and both are observed to read 0. $B^{\bullet} t' = t'_1$ (event E_1) $H^{\bullet} t = t_1$

Here H is adjacent to B, H is observed to read t_1 and B to read t'_1 .

Here A is adjacent to N, A is observed to read t_2 and N

All this is quite independent of theory: it is a simple description of a possible physical process. A theory is required when we wish to determine two independent things: (i) the values of t'_1 , t'_2 for given values of t_1 , t_2 , or vice versa; and (ii) the relative rates of A and B which these values imply.

Now apply Einstein's theory⁴, supposing A fixed at the origin of the K co-ordinate system and B fixed at the origin of the k system.

(i) t and t' are related by the Lorentz transformation, so that

$$t_1' = at_1 \tag{1}$$

(ii) This is determined by choosing a pair of events and comparing the intervals between the readings of A and B at those events.

Einstein chose events E_0 and E_1 . At these events A reads 0 and t_1 , respectively, and B reads 0 and t'_1 , respectively. The reason why A must be held to read t_1 at E_1 is that H reads t_1 at this event, and on this theory the process by which A is set in relation to H synchronizes it with H.

Thus, between events E_0 and E_1 , A advances by t_1 and B by $t'_1 = at_1$ by (1). Therefore

$$\frac{\text{rate of } A}{\text{rate of } B} = \frac{t_1}{at_1} = 1/a > 1 \tag{3}$$

 $\frac{\text{rate of } A}{\text{rate of } B} = \frac{t_1}{at_1} = 1/a > 1$ But now choose events E_0 and E_2 . At these events A reads 0 and t_2 , respectively, and B reads 0 and t'_2 . respectively. The reason why B must be held to read t_2' at E_2 is that N reads t_2' at this event, and on this theory the process by which B is set in relation to N synchronizes it with N.

Thus, between events E_0 and E_2 , B advances by t_2' and A by $t_2 = at_2'$ by (2). Therefore

$$\frac{\text{rate of } A}{\text{rate of } B} = \frac{at_2'}{t_2'} = \alpha < 1 \tag{4}$$

Equations (3) and (4) are contradictory: nence the theory requiring them must be false. Einstein4, in his paper, gave only (3), and accepted it as giving the unique value of the rate-ratio: he did not check the result by considering the interval between E_0 and E_2 . Had he done so he would undoubtedly have seen that his conclusion was erroneous.

I regard this as a conclusive proof that the special relativity theory is untenable, and the consequences of this fact, however improbable they may seem now (they would certainly not have seemed so in 1905), must therefore be accepted. The resistance to acceptance arises not from reason, as my long experience shows, but from incredulity, and this, in its turn, from some very deep-seated misapprehensions which it is impossible here to explore fully, but which can be indicated sufficiently, I hope, to remove something of the almost compulsive predisposition to regard criticism of special relativity as necessarily misconceived.

(I) It is often held that the logical structure of the theory is unassailable, and therefore the theory can be disproved, if at all, only by experiment: hence, any such paper disproof as the foregoing must necessarily be fallacious and there is no need to waste time in discovering where the fallacy lies. This was expressed by Professor Max Born, in the letter previously referred to, in the following terms²: "The simple fact that all relations between space co-ordinates and time expressed by the Lorentz transformation can be represented geometrically by Minkowski diagrams should suffice to show that there can be no logical contradiction in the theory."

The error here lies in oversight of the fact that a physical theory must contain not only a mathematical structure but also a correlation between the mathematical symbols and observable quantities: a perfectly logical theory may therefore fail physically in the second of these requirements. This oversight calls for much more general consideration, because it characterizes almost the whole of modern physical theory, in which so often a mathematical possibility is assumed automatically to be a physical possibility also, whereas mathematical symbols have a far wider range of significance than is possible to the physical objects whose properties they are taken to represent. This is a matter for later discussion: here I must restrict myself to a single example showing the inapplicability of Professor Born's statement.

The equations, 8-6=2 and 6-8=-2, are mathematically valid and equivalent examples of the general equation, a-b=c. They are both geometrically applicable to a physical situation: thus, if we walk 8 miles north (+) and then 6 miles south (-) we end 2 miles north of our starting point; and if we walk 6 miles north and then 8 miles south we end 2 miles south of our starting point. But they are not both applicable to physical objects: you can get 6 apples from 8 by leaving 2 behind, but you cannot get 8 apples from 6 by leaving -2 behind, but you cannot get 8 apples from 6 by leaving -2 behind. If Professor Born's argument were sound we should be able to say: the simple fact that all numerical values of a, b and c expressed by the equation a-b=c can be represented geometrically by lines drawn to north and south should suffice to show that there can be no logical contradiction (and, by implication, nothing wrong) in the theory that you can get 8 apples from 6.

(II) The resistance most commonly felt by practical physicists to the disproof of the theory arises from a conviction that the experimental evidence for it is too strong to be overcome by a mere piece of logical jugglery which, in face of it, has no more weight than Zeno's proof that Achilles could not overtake the tortoise. This again reveals a misconception needing far more extended treatment than is possible here, where all that can be said is that it is due to an oversight or misreading of the facts of history. There is no existing experimental evidence for Einstein's theory that does not give exactly the same support (whatever that may be) to a quite different theory advanced earlier by Lorentz⁵. Both theories have the same mathematical structure (the Maxwell-Lorentz electromagnetic equations plus the equations of the Lorentz transformation) but give it All that the quite different physical interpretations. experiments so far performed (for example, those showing increase of mass with velocity, extended lifetimes of cosmic ray particles, etc.) show is that if we assume the electromagnetic equations we must correct them by the Lorentz transformation; they throw no light at all on the physical interpretation of the equations.

The physical differences between the theories are profound: here are a few. Lorentz ascribes the contraction of rods and slowing down of clocks to an *ad hoc* physical effect of the ether on moving bodies; Einstein

ascribes them to an ad hoc modification of kinematics at high velocities. Lorentz's theory is impossible without an ether; Einstein's (because of its relativity postulate) is impossible with one. Einstein's theory makes a velocity greater than c logically impossible; Lorentz specifically restricted his theory to "a system moving with any velocity less than that of light", and, from the nature of its effects, it must break down well short of that velocity, just as Boyle's law breaks down well before the volume of a gas shrinks to nothing; it makes the "light barrier" no more necessarily impassable than the "sound barrier". Einstein's theory merges space and time into an unimaginable "space-time"; Lorentz's leaves them independent, as in ordinary understanding. The physical consequences of these differences when very high macroscopic velocities are attained are enormous and ominously incalculable.

Until the First World War, Lorentz's and Einstein's theories were regarded as different forms of the same idea, but Lorentz, having priority and being a more established figure speaking a more familiar language, was credited with it: thus Poincaré, as late as 1912, spoke of "le principe de relativité de Lorentz", even in a paper in which he was discussing Einstein's view of the action of light on molecules. It was not until 1919, when the eclipse observations compelled acceptance of Einstein's general theory, that "the special theory of relativity" became uniquely ascribed to Einstein, and the ideas associated with the name in the minds of physicists became an incompatible mixture of Lorentz's and Einstein's—a fact that preserved the theory from disproof, since any attack on the relativity aspect could be met by an appeal to Lorentz's non-relativistic ideas, and criticisms of those could be disposed of by a reversion to relativity. Thus, for example, the "FitzGerald contraction" was variously regarded as an actual physical effect and as a mere appearance, according to the needs of the occasion.

Whittaker' partly exposed the confusion, but, as a pure mathematician characterizing a theory by its mathematics alone, he saw it as merely a wrong assignment of priorities, and entitled his chapter on the supposedly single theory, "The Relativity Theory of Poincaré and Lorentz". The fact that there were two distinct theories, physically poles apart, was thus obscured. If Einstein's paper, however, had never been written, all the experiments now held to "prove" Einstein's theory would still have been performed and held with the same conviction to prove Lorentz's. Is it conceivable, it would have been asked, that a moving body can experience a resistance to acceleration (increase of mass) unless there is an ether to provide the resistance? Indeed, this very phenomenon was cited by Lorentz in support of his theory before Einstein's paper appeared. The very experiments now held to prove a theory dismissing the ether would have been held to prove its indispensability.

An important point in the present discussion, however, is that the disproof of Einstein's theory given above leaves Lorentz's intact. Both agree down to equations (1) and (2), but the process by which, according to Einstein, A and H, and B and N, respectively, are synchronized does not synchronize them on Lorentz's theory, because one pair, at least, must be moving in the ether. If we suppose the other pair at rest, then they are truly synchronized, but the moving pair are not, any more than clocks on relatively stationary aeroplanes, moving rapidly through the air along the line joining them, would be synchronized by a similar process with sound waves. If, then, we attach conclusive weight to already performed experiments, we must consider Lorentz's theory proved and seek a rational basis for his ad hoc postulates.

But those experiments are not conclusive, for they do not dispose of the alternative possibility, advanced by Ritz, that the velocity of light is c with respect to its source alone. Einstein's theory is a logical deduction

from two postulates: (a) the postulate of relativity the absence of an absolute standard of rest, that is, of an ether, and (b) the postulate that the velocity of light in space is c, whatever the motion of its source. Lorentz's theory denies (a) and accepts (b); Ritz's theory accepts (a) and denies (b). Contrary to general belief, Ritz's theory (that is, the simple hypothesis just stated, not necessarily his tentative development of it, which he later described as a "Scheusal-Theorie"—horror theory) has never been tested. Deductions from double star observations are inconclusive10, and the various laboratory experiments with hypothetical particles as sources and the assumption of the wave equation, $c=n\lambda$, with its usual interpretation, all involve a circular argument. If Ritz's hypothesis is correct, the electromagnetic theory of light, in its present form at least, is not, for that requires the velocity of light to be independent of that of its source. Thus we must not presuppose any part of the electromagnetic theory in testing Ritz's hypothesis. But all tests involving hypothetical particles, or interference as it is usually understood, do just that. To take but one example, in the experiment of Alväger, Nilsson and Kjellman¹¹, beams of γ-radiation from a vacuum tube, showing spectrum shifts suggesting sources moving with high velocity, travelled through space with the same velocity as beams from particles in the tube showing no spectrum shift, and it was concluded that Ritz's hypothesis was disproved. But suppose the beams had travelled with different velocities. Then the electromagnetic theory would have been disproved, and so the evidence that the sources were particles moving with the supposed velocities would have disappeared. Such an experiment therefore could not possibly have tested Ritz's hypothesis. For a true test the source must be a body observed to move with a known velocity and not one inferred from a theory that rules the hypothesis out of court before the test has begun.

The following aspect of the situation may clarify it for some readers. The Maxwell-Lorentz electromagnetic equations and the Newtonian mechanical equations had in common the co-ordinates (x, y, z, t) which were related to space and time measurements in an understood way, and their values when the physical system under consideration was referred to a relatively moving system of co-ordinates were taken, in 1905, to be given by the Galilean transformation. This left the mechanical equations unchanged in form (that is, they were relativistic), but not the electromagnetic equations. ("The [electromagnetic] theory appeared to be unsatisfactory only in one point of fundamental importance. It appeared to give preference to one system of co-ordinates of a particular state of motion. . . . In this point the theory seemed to stand in direct opposition to classical mechanics, in which all inertial systems which are in uniform motion with respect to each other are equally justifiable as systems of co-ordinates"12.) Electromagnetic theory was accordingly taken to require certain observable events to occur (for example, a fringe-shift in the Michelson-Morley experiment) when a piece of apparatus was moved. In fact these events did not occur, that is, electromagnetic phenomena were relativistic (invariant to motion), but the equations were not. The latter, however, would be relativistic if the transformation equations were not those of Galileo but those of Lorentz. Einstein's theory was that they were so, and the effect of this on mechanics was then far beyond the possibility of experimental test because the necessary velocities in a mechanical experiment were unattainable.

But if the Galilean transformation is the correct one, the assumption of the Lorentz transformation must give discrepancies with observation in mechanics corresponding to those found in electromagnetism under the Galilean transformation. This is what is now shown to be the case; the assumption of the Lorentz transformation in mechanics requires one clock to work both faster and slower than another. The fact that this can be seen to be contradictory in advance of observation, whereas the result of the Michelson-Morley experiment could not be foreseen, is due simply to the fact that we already know far more about clocks than about light. Whether or not a particular mathematical possibility can be realized physically can be known prior to experiment only when we have sufficient knowledge of the physical situation concerned, and we know enough about clocks to know that one cannot, at the same time and in the same sense, be working both faster and slower than another. If we had as much knowledge of the structure and behaviour of light sources and light beams as we have of clocks (or apples), a fringe shift in the Michelson-Morley experiment would be as obviously impossible as the contradictory behaviour of clocks (or the obtaining of apples by the compensating creation of negative ones). And, just as the Michelson-Morley experiment is only one of a number showing the breakdown of electromagnetic theory under the Galilean transformation, so the experiment with moving clocks is only one of a number showing the breakdown of mechanical theory under the Lorentz transformation. Another, for example, is revealed in the possibilities of mutual observation by widely separated observers¹³. It is clear that a change of transformation equations, as proposed by Einstein, merely transfers the discrepancy with observation from one set of phenomena to the other: a change in the theory of one set (almost certainly electromagnetism, as quantum phenomena more than suggest), by giving the ether additional properties (Lorentz) or discarding it (Ritz) or by some other means not yet conceived, would now seem to be the only possibilities open of reconciling mechanical and electromagnetic phenomena in a single theory (which may or may not be a unified field theory).

The net result, then, of these considerations concerning experiments is that none yet performed disproves either Lorentz's or Ritz's theory, and because neither theory is disproved by the earlier rational argument which was fatal to Einstein's (on Ritz's hypothesis, equations (1) and (2) become simply $t_1' = t_1$ and $t_2 = t_2'$, leading to a rateratio of unity for all event-intervals), these theories remain in the field. A valid experiment to test Ritz's hypothesis (such, for example, as that suggested earlier to which observable sources are used) is clearly called for.

(III) Another apparent possibility of saving Einstein's theory lies in the supposition that equations (3) and (4) are not really contradictory because they refer not to objective phenomena but merely to appearances: A appears to go slow when observed from B, and B appears to go slow when observed from A. Again it would take too much space to show—although I do not think anyone familiar with the subject will have much difficulty in perceiving it—that if this were so the whole theory would be concerned merely with appearances and could not possibly lead to an explanation of any of the objective phenomena for which the theory was designed. All that is practicable here is to point out that this was not Einstein's interpretation of the result, nor has it been that of any of his followers when dealing with this point alone and not seeking an interpretation that will dispose of some other difficulty. Here are the deductions which Einstein makes from equation (3)4: "If one of two synchronous clocks at A is moved in a closed curve with constant velocity until it returns to A, the journey lasting t seconds, then by the clock which has remained at rest the travelled clock on its arrival at A will be $\frac{1}{2}tv^2/c^2$ second slow. Thence we conclude that a balance-clock at the equator must go more slowly, by a very small amount, than a precisely similar clock situated at one of the poles under otherwise identical conditions". We need not ask if these deductions are valid; all we need to notice is that precisely the opposite deductions, valid or invalid, can be made from equation (4). It is inconceivable that if Einstein had noticed this he would have selected only the equatorial clock as the one which was going slower than the other. Moreover, he

added a footnote to say that the result did not apply to a pendulum clock. This would have been meaningless if it were not the actual physical working of the clocks that was in question but merely an accident of the observer's standpoint. As evidence that the general interpretation of the result agrees with Einstein's, it is sufficient to cite the universal belief that asymmetrical ageing of separated and reunited clocks or persons is required by Einstein's

Allied to this is the misconception that equations (3) and (4) refer to different physical situations. That is not so. The events E_0 , E_1 , E_2 , are successive events in a single process; there is no change in the physical conditions during that process. Also, there is no "change of co-ordinate system". Such systems appear in the argument only implicitly in the use of the Lorentz transformation to derive equations (1) and (2), and there is no change of system anywhere in the derivation. Whether you regard A as stationary and B as moving, or vice versa, makes no difference whatever: throughout, the primed symbols refer to the clocks B and N and the unprimed symbols to the clocks A and H, no matter how you describe them.

The situation is quite clear: the only difference between the arguments leading to (3) and (4) is in the events chosen for comparing the clock rates. If Eintsein's theory is valid the following questions arise. How is it possible for the ratio of the intervals recorded by two identically constructed, regularly running, clocks, between the same pair of events, to vary with the events chosen (in other words, how can the ratio of two constant quantities be variable)? Second, if it is possible, why must the events that alone give the "correct" ratio be chosen from the set occurring on one and not the other of the clocks? Third, if they must be so chosen, how does one (consistently with a theory in which the only feature in which the clocks differ-motion-can be ascribed indifferently to one or the other) discover on which clock the valid set of events occurs? I think it is self-evident that these questions are unanswerable. There can be no doubt that, if this criticism of the theory had been made in 1906, it would at once have been seen to be fatal and Einstein would have been the first to acknowledge it, for then reason was the de facto as well as the de jure arbiter in such a matter. In 1967, however, the obvious has become the inconceivable, and it has to meet the prejudice, independent of reason, that every apparent objection to special relativity is merely evidence of incomprehension and can accordingly be ignored. Unless faith in reason is restored, and prejudice determinedly uprooted, the outlook in the present age is black indeed.

I have introduced a discussion of the implications of the matter, not at present for their own sake but in order to remove obstacles, which experience has shown to be formidable, to concentration of attention on the simple alleged disproof of the theory. I hope it will not have the opposite effect of diverting attention to itself. As I have said, most of the points raised demand fuller treatment

later. But the disproof is complete in itself. Unless some specific error is found, and clearly exposed, in the passage of the foregoing argument extending from the words, "Now apply Einstein's thoery ..." to "... hence the theory requiring them must be false"—an error of such a character that it invalidates equation (4) without, at the same time, invalidating equation (3)—it must be accepted that the special relativity theory is untenable, no matter how unexpected or unwelcome or perplexing or fraught with difficulties the implications and consequences may be.

I would point out also that what I have advanced is not a theory which, in the traditional scientific manner, can be left to be justified or condemned by experiment. No experiment can do either, for the conclusion follows rationally from the premises. If there is no error in the reasoning, the only relevant experiments—and they are urgently demanded-are those designed to show where, and not if, the theory is wrong. Furthermore, it does not seem yet to be sufficiently realized that the nature of modern experiments makes imperative a change of attitude to the relegation of fundamental problems to decision by experiment. It was safe enough to await a measurement of the velocity of light through air and water before deciding for the wave or particle theory of light, and the convincing nature of the result justified suspension of judgment. But, so deeply involved are the special relativity theory and the electromagnetic theory of light in the whole of modern physics, that if experiments of the modern type continue on the assumption that special relativity is tenable when it is not, the results, sooner or later, are as likely as not to lay waste a county. Truth is immortal but human lives are not, and they have claims to protection, even at the cost of admitting an error in physical theory that should never have been made. The recent tragedy at Aberfan shows how bitterly regrettable the consequences may be when hindsight is not anticipated by foresight, and the consequences there were slight compared with those conceivable here. I hope, therefore, that this matter will no longer be allowed, by neglect, to take its own natural and possibly disastrous course, but will be faced squarely and promptly, with no aim but that of arriving at the truth, whatever it may be.

Why the Special Theory of Relativity is Correct

by W. H. McCREA

I give first a brief presentation designed to facilitate a reply to Professor Dingle's present statement and to the one1 he gave in 1962. So far as applicable, I use Dingle's present notation (which is not identical with what he used in 1962).

Let Ox be a rigid rod graduated in the usual way; let similar clocks be fixed to the rod at points along the rod, and let them be synchronized by a standard procedure (that described by Dingle). If anything happens at the position x of any one of the clocks, let t be the reading of that clock at that event E, say. We speak of the event E

as the event (x, t). Let O'x' be a second rigid rod in motion along Ox with uniform velocity $v \neq 0$. Let Ox' be graduated in the same way as Ox; let clocks similar to those attached to Ox be fixed to O'x' at points along O'x', and let them be synchronized amongst themselves by the standard procedure. If anything happens at the position x' of any one of these clocks, let t' be the reading of that clock at that event E', say. We speak of the event E'as the event (x', t').

According to the theory of special relativity, this system is possible, supposing Ox, O'x' to belong to inertial frames K, k, say. The theory then asserts that E, E' are one and the same event if and only if the parameters satisfy the relations

$$at' = t - vx/c^2 \tag{I}$$

$$at = t' + vx'/c^2 \tag{II}$$

E

where $a = (1 - v^2/c^2)^{\frac{1}{2}}$, supposing 0 < a < 1 and supposing the zero points of the various quantities are suitably chosen. This is one way of writing the Lorentz transformation (being the one used by Dingle in his earlier paper¹).

Consider in k the particular clock B permanently fixed at O', so that every event at B has x'=0. Then from (II) for every such event

$$at = t'$$
 (III)

[Take, for example, the case $a=\frac{1}{2}$. Equation (III) means that if clock B reads t' then that K-clock past which B is moving reads 2 t'; at 1 o'clock by B it passes a K-clock reading 2 o'clock, at 2 o'clock by B it passes a K-clock (a different one, naturally) reading 4 o'clock, and so on.]

In the immediate operational interpretation of (III), as just illustrated, t' is the reading of one and only one clock and t is the reading of a different clock for each different value of t. I repeat that, so far as our discussion is concerned, every event to which (III) applies happens to clock B.

If we next consider in K the particular clock A permanently fixed at O, then every event at A has x=0 and from (I) we have for every such event

$$at' = t$$
 (IV)

This is obviously what we expect from (III) because now K, k have exchanged roles. In (IV), t is now the reading of one and only one clock, and t' is now the reading of a different clock for each different value of t'. Manifestly the parameters t, t' do not have the same meanings in (III), (IV). Every event to which (III) applies happens to the clock B; every event to which (IV) applies happens to the clock A.

[If we do require both (III) and (IV) to hold good we get simply t=0=t', since $a^2\neq 1$. That is, (III), (IV) are both satisfied for the unique event that happens to both clock A and clock B, namely their single mutual encounter. This is obviously entirely consistent with what has just been said.]

No particular or preferred observer is concerned in these results. If a cine-camera anywhere in any state of motion takes a sequence of pictures of clock B, each picture will show clock B with some reading t' and, adjacent to B, a K-clock reading t'/a, the K-clock being a different one in each picture. If the same or any other camera takes pictures of A, each picture will show A with some reading t and, adjacent to A, a k-clock reading t/a, the k-clock being a different one in each picture.

I turn now to Dingle's allegation that the theory used above "must be false". In his present paper, this is based simply on his claim to have inferred the contradictory statements (3) and (4) of his paper from the theory. So we have to do only with the logical consistency of the theory. It may help if I enumerate a sequence of arguments; the first alone is sufficient to refute Dingle's contention, but I hope the rest throw further light on the subject as a whole.

(i) Dingle's assertion is obviously and demonstrably wrong. Using no more than the Lorentz transformation in his algebra, he claims to derive two different values for the same quantity. But the transformation is linear and any result it gives can only be unique. It is trivially impossible for it to give two different answers to the same question. If Dingle obtains two different answers it must be because (a) he has made a slip in the algebra, or (b) his quantities are not well defined, or (c) what he treats as the same quantity are two different quantities.

(ii) Dingle has not made any mistake in the algebra, but in his present paper he deals with objects to which the theory explicitly denies a meaning. We consider events E_0 , E_1 , E_2 defined and described in frames K, k as follows (these being apparently the events similarly denoted by Dingle):

Event	K-description	k-description
E_0 A, B encounter each other	x = 0, t = 0	x' = 0, $t' = 0$
E_1 , H , B encounter each other	$x=x_1, t=t_1$	$x'=0$, $t'=at_1$
E_2 A, N encounter each other	$x=0$, $t=at'_{B}$	$x' = x_2' l' = l_2'$

Here, and in physics generally, event means something happening at a particular position at a particular instant. The crucial feature is that an observer experiences an event if, and only if, the event is part of his own history, that is the event is in his own world-line.

In Dingle's system in his present article A and B are the only observers who experience the event E_0 , or are "at" event E_0 ; H and B are the only observers at E_1 ; A and N are the only observers at E_2 . Dingle arrives at his conclusions because in practice he does not adhere to the standard concept of an event. He asserts, "The reason why A must be held to read t_1 at E_1 is that H reads t_1 at this event, and on this theory the process by which A is set in relation to H synchronizes it with H... The reason why B must be held to read t_2 at E_2 is ...". A is not "at" E_1 in any sense admitted by the theory and it simply has no meaning whatever within the theory to speak of what A must be held to do at E_1 . B is not at E_2 and it has no meaning to speak of what B must be held to do at E_2 .

Just before his formula (3), Dingle proceeds to state "between events E_0 and E_1 , A advances by t_1 . . .". Because A is never at E_1 , this phrase is meaningless and so Dingle's (3) is meaningless. Correspondingly his (4) is meaningless.

(iii) Naturally there is an event E_{1A} , say, at which A reads t_1 . This event has x=0, $t=t_1$ and so clearly $E_{1A} \neq E_1$, thus corroborating what has just been said.

(iv) Dingle's language requires a meaning for what the clock A reads "at" some event involving B even though A is not at the place of that event. In other words, he wants to say what A does "when" B does something, although A and B are not adjacent. Indeed, Dingle expressly uses this phraseology in his 1962 paper. But this restores the notion of distant simultaneity.

About the first thing that relativity theory does is to deny any operational meaning to the notion of simultaneity at two different places. Naturally, this fundamental feature in the theory is not affected in the slightest by any arbitrary conventions we may adopt for the synchronization of clocks. The latter is merely a particular way of putting the readings of two relatively stationary clocks into 1–1 correspondence with each other.

(v) While Dingle's (3) and (4) are meaningless as they stand, the quantities involved can of course be assigned operational meanings in terms of readings of the relatively moving clocks A, B. The formulae do not then tell us about the "rates" of the clocks. They become simply two different ways of putting the readings of A, B into 1-1 correspondence with each other. There are infinitely many different ways of doing this! Being no more than ways of attaching labels, there can be no question of any two of these ways being "contradictory".

these ways being "contradictory".

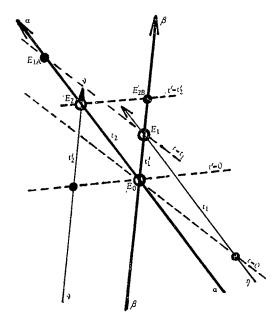

(vi) In his 1962 paper, Dingle started from equations (I), (II) as we have written them (but in his earlier notation) and then derived precisely our equations (III), (IV). He then asserted, "every symbol has exactly the same meaning in both cases", and he claimed to infer a contradiction. His assertion is false, because here he is not talking about the same thing, but two different things. As we have seen, equations (III) and (IV) concern two distinct sets of events, and so they cannot contradict each other. More exactly, the equations concern distinct sets apart from the unique common event for which t=0 and t'=0, and for this event (III) and (IV) are clearly both satisfied.

(vii) While in Dingle's system A and B are the only observers who experience event E_0 , it is of course meaningful to say that other observers can observe event E_0 . Indeed, if any observer Ω anywhere in the universe takes a motion picture of A or B and if one exposure shows the encounter of A with B, then we say that Ω has observed the event E_0 . This exposure would show A and B in juxtaposition with both clocks in this case reading zero. Every observer who observes E_0 will get precisely this same picture.

Suppose now that the motion picture taken by Ω shows also the clocks H, N of Dingle's system. Then in the exposure showing the event E_0 , clocks H, N will appear showing some particular readings. If another observer Ω^* at some different place in the universe makes a corresponding motion picture, then in Ω^* 's exposure showing the event E_0 clocks H, N will appear showing some other particular readings different (in general) from those in Ω 's exposure. This is because the various light-travel times from the clocks to Ω and to Ω^* are all different. Thus there is no unique reading, and no preferred reading, of H or of N to be associated with the event E_0 . This inference does not depend on any arbitrarily selected graduation of the clocks. Thus we have another, possibly more "operational", refutation of Dingle's criticism.

(viii) We may draw a simple space-time diagram in which α is the world-line of A, and so on. Then the events E_0 , E_1 , E_2 are as shown. This makes it perfectly clear that α does not go through E_1 and so there cannot possibly be a reading of A "at" E_1 , this having nothing to do with the manner in which the clocks happen to be graduated. This was the essential point of Born's comment².

In this diagram we may treat t, t' as oblique cartesian co-ordinates. Then, using these co-ordinates, equation (III) is the equation of the world-line β and equation (IV) is the equation of the world-line α and E_0 is their unique point (0,0) of intersection. This shows more clearly than any-

thing else the difference between the two sets of events for which (III) and (IV) hold good.

The diagram shows the line $t=t_1$ through E_1 meeting α in the event E_{1A} . Thus E_{1A} is the event at which A reads t_1 . As we have said, Dingle's formula (3) has to do with the correspondence between events E_1 , E_{1A} ; but we learn nothing by setting up this correspondence and so there is nothing in it to be contradicted, or to contradict anything else.

Fluidization

by J. B. LEWIS B. A. PARTRIDGE

Chemical Engineering and Process Technology Division, AERE, Harwell

Industry is making increasing use of gas and liquid fluidization, but the theory behind the process is imperfectly understood. Improved application of some earlier techniques, however, is beginning to reveal something of the behaviour of bubbles and solids during gas fluidization.

"FLUIDIZATION" is a good example of an industrial process which is widely used although the underlying science is imperfectly understood. In a "fluidized bed" a mass of solid particles is made mobile by means of an upward flow of gas or liquid, and the pressure drop through the bed balances its weight. The bed behaves like a liquid, there is good mixing of solids, a uniform temperature distribution and excellent heat transfer between the walls and the gas or liquid. These properties make the use of fluidized beds attractive for many operations where solids are contacted with gases or liquids especially if close temperature control is important. Gas fluidized beds are much more commonly used than liquid fluidized beds although the latter are employed in some water treatment and ore leaching processes. The first uses of gas fluidized beds were concerned with ore roasting and coal combustion, but during the past 25 years they have become very widely used in a variety of catalytic processes; the well known "cat cracker" was the first of these.

The nature of the solids movement obtained when the fluidizing medium is a gas is different from that produced by a liquid. In the latter case, as the liquid velocity is

increased beyond the value necessary to support the bed this flow rate is known as the minimum fluidization velocity or U_{mf} —the particles separate from each other and begin to move about the bed in a complex manner in response to eddies in the liquid flow. The bed expands and continues to do so progressively, if the liquid velocity is further increased, until ultimately the individual particles are carried out of the bed. In a gas fluidized bed, on the other hand, as the gas velocity is increased beyond U_{mf} , the bed expands only to a very limited extent before it becomes unstable and voids or bubbles of gas are formed. These bubbles pass upwards through the bed in a manner very similar to bubbles rising in a liquid. Any further increase in the gas flow rate leads to the formation of more bubbles. The bed thus consists of two regions, or phases, the bubble phase and the dense phase, which has a density very close to that of the bed at U_{mf} and through which gas passes interstitially at a flow rate close to U_{mf} . Although the movement of particles is rapid and appears to be quite random, it is only a complex repetition of a motion resulting from the rise of bubbles through the bed. Each bubble draws up a "spout" of particles behind it, and this upward flow is compensated by a steady downward drift elsewhere in the bed.

There is a certain amount of overlap between the behaviour of the liquid fluidized and gas fluidized type of bed. Light particles of less than about 50µ diameter exhibit a limited degree of liquid bed-type expansion while, on the other hand, liquid voids are obtained when very dense media such as lead or tungsten powder are

fluidized by liquids.

Because of the greater use of gas fluidized beds, their ever increasing size and cost, and the more complicated flow pattern obtained in them, they have been much more widely investigated than liquid fluidized beds. Nevertheless, much empiricism is still necessary in their design. Empirical measurements are expensive and time consuming to carry out on the scale necessary and there is thus a considerable financial incentive to obtain a better understanding of the factors controlling the performance of gas fluidized beds.

The first step in designing a gas fluidized bed is to know the minimum fluidizing velocity of the bed material. Typical values for spherical particles are 0.3 cm/sec for a silica-alumina catalyst of less than 0.1 mm diameter and 40 cm/sec for copper shot of 0.4 mm diameter Although various semi-empirical correlations have been developed from which U_{mf} can be calculated, these can often be unreliable when applied to industrial materials,

and the value is best measured experimentally.

In most cases it is necessary to operate gas fluidized beds at gas velocities in excess of U_{mf} in order to obtain sufficiently rapid solids mixing and good rates of heat transfer from wall to bed. Because a large fraction of the gas is then passing through as bubbles it is important to know how effectively this gas contacts the solid. Until recently there was no direct evidence at all on this point and such information as existed came from a study of the "overall" behaviour of the bed using a variety of "models" to explain the results. In these models it was generally assumed that the solids were perfectly mixed with the gas passing through in plug flow, but in two One stream comprised the gas flowing interstitially through the dense phase at approximately U_{mf} , the other being the gas passing through as bubbles and which was thought to have little contact with the solids. Some interchange of gas between these two phases was assumed to take place and the extent of this interchange was determined experimentally in some cases by injecting a pulse of a suitable tracer gas into the fluidizing gas and examining the attenuation of the emergent pulse. The results obtained, however, were often difficult to interpret unambiguously and extrapolation of the results obtained in one bed to another was very speculative.

Much of the basic investigation into the behaviour of gas fluidized beds has been carried out in small laboratory equipment a few inches in diameter. Because, however, bubbles I ft. or more in diameter are frequently encountered in industrial practice the interpretation of the laboratory experiments is sometimes suspect. Various types of probes have been inserted into experimental, and operating, gas fluidized beds to identify the bubble pattern within. These have depended on the change produced in the optical density, local heat transfer and, especially, dielectric constant, of the bed when a gas bubble surrounds the probe. The picture is usually complicated and often confused. Probes have also been used to investigate particle movement and changes in

the density of the particulate phase.

More recently, direct unambiguous information about the behaviour of bubbles and of the dense phase has been obtained by the use of two complementary techniques. Neither technique is new but previously they had not been used to the best advantage. The first is the use of "two dimensional" fluidized beds. Such beds, which may be up to 10 ft. high and 2 ft. wide, are only about 0.5 in. thick, so that the bubbles span the gap between the trans-

parent walls and are visible as shown in Fig. 1. Although at first sight one might expect a large "wall effect", which would affect the flow pattern, in fact, whenever a direct comparison has been possible between a two dimensional bed and a conventional bed the flow patterns have been found to be essentially similar. The use of a coloured gas, such as nitrogen dioxide, enables the gas flow pattern to be seen directly and the corresponding use of coloured particles demonstrates the solids movement. In addition, changes in the density of the dense phase can be measured using X-ray or γ-ray attenuation. The second technique is the use of X-ray cinephotography to observe the shape and velocity of bubbles in a cylindrical bed, typically of 6 in. diameter. By using solids of different X-ray opacity the particle movement can also be seen. With each of these techniques considerable advantage has been obtained by studying the bed with a single bubble rising through it. In this way the basic patterns of gas flow and particle movement associated with a bubble have been discovered and can be applied to the more complex situation of a bed in which many bubbles are present.

These techniques, which were developed principally at AERE, Harwell, have shown that the solids are not in random movement but are displaced in an ordered manner by the bubbles as they rise through the bed. The bubbles, which are empty of particles, are essentially spherical (or cylindrical in a two dimensional bed) except for an indented base. As a bubble rises the particles flow around

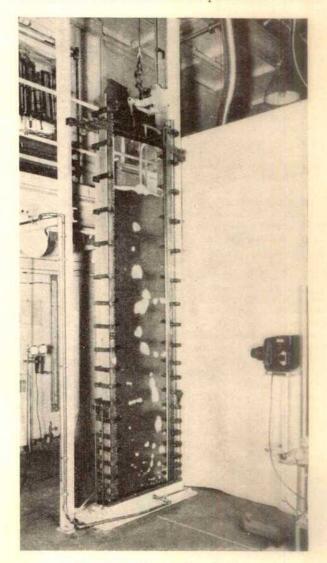

Fig. 1. View of large two dimensional bed.

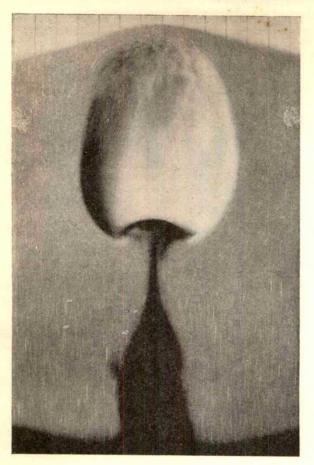

Fig. 2. Wake and drift profile associated with a rising bubble,

it in streamline motion and as a direct consequence each horizontal layer of particles is displaced into the classical 'drift profile" that is characteristic of this type of streamline motion. In addition to this, the indented base of the bubble, constituting about the lower quarter of the sphere volume, contains a "wake" of circulating particles that are travelling with the bubble. A photograph of a bubble in a two dimensional bed is shown in Fig. 2. The drift profile and wake are visible because the bubble has passed from the lower region of the bed, which contains dark coloured particles, up into the lighter coloured upper region. Experiments have shown that the particles in the wake are more widely spaced than in the rest of the dense phase. The wake is unstable and periodically sheds material and re-forms as the bubble rises. Eventually it is deposited on the surface of the bed. Thus particles are progressively carried up from the bottom of the bed to the top. If the bubble pattern is ordered, then so is the solids flow pattern. Because of the rapid bubble flow in most industrial beds the overall result is very similar to perfect mixing, but the difference between truly random mixing and bubble mixing can be significant where the local flow of solids is important.

The two dimensional gas flow studies have shown that the gas flow pattern associated with a bubble is critically dependent on the ratio, α , of the bubble velocity to U_{mf} . The latter generally varies as the square of the particle diameter, whereas the bubble rising velocity is relatively independent of the bed material and, like a gas bubble in an inviscid liquid, depends on the square root of its diameter. Thus, in a bed of large particles (usually this means particles greater than about 350μ in diameter) U_{mf} will be greater than the bubble velocity and $\alpha < 1$, whereas in finer materials U_{mf} will be much less and $\alpha > 1$. The former is the normal state of affairs in beds

containing large lumps of, for example, coal, while the latter state exists in beds of catalyst particles. When a is less than unity interstitial gas passes into the base of the bubble and out through the roof. Thus the gas comprising the bubble is continually changing and it is incorrect to consider the bubbles as forming a separate stream of gas. When a is greater than unity a region of gas recirculation, termed the gas cloud, is formed around the bubble. The gas in the bubble recirculates continually through the bubble as it rises penetrating only a limited distance into the dense phase. The extent of this penetration diminishes as a increases until at a values greater than about 10 the cloud boundary virtually coincides with the bubble boundary. The bubble gas only mixes with the solids in this penetration region, and so the smaller the cloud the poorer the contacting efficiency. Some exchange does take place, however, between the cloud and the interstitial gas because of molecular diffusion and also because of an imperfectly understood "cloud shedding" phenomenon. In Fig. 3 a gas cloud, of nitrogen dioxide, is shown around a bubble travelling in an air fluidized bed at an α value of 2.5. Some gas which has been shed from the cloud can be seen below the bubble.

The existence of this cloud was predicted by Davidson' as a result of calculations based on a simple model representing the hydrodynamics of gas flow in the dense phase adjacent to a rising bubble. More sophisticated models have since been proposed by Jackson² and Murray³. These enable the size of the cloud to be calculated more accurately and it is now possible to predict with a fair degree of confidence the efficiency of gas—solids contacting in a bed if the bubble velocity and U_{mf} are known. The former can be calculated from the bubble size and the latter from the particle size. Unfortunately, no satisfactory theory exists which enables the bubble size distribution in a bed to be predicted. Thus, either the bubble size must be guessed or else empirical measurements made.

Observations of the behaviour of rising bubbles, both in the two dimensional bed and also by the X-ray technique, show that they are continually splitting up and coalescing. A protuberance forms on the roof of a bubble and cuts the bubble into two as it rises. Bubble splitting in this way sometimes results in the formation of two separate bubbles, but very often a rapid recoalescence of the "daughter" bubbles occurs. In addition, the coales-

cence of separate bubbles occurs very frequently so that the average bubble size increases with height in the bed. Bubble size can play a vital part in determining the efficiency of gas-solids contact in many circumstances and it is therefore important to be able to predict the size and pattern of bubbles that will be formed in a given situation. This is an important, and difficult, aspect of fluidization on which further research is badly needed.

When a is greater than unity the extent of gas interchange between the cloud and the interstitial gas will markedly affect the efficiency of gas-solids contacting. At present the magnitude of this exchange can only be estimated and here again there is a need for further

research to explain this phenomenon.

Apart from these two important areas of ignorance there remain many other interesting features of the gas fluidized bed that would repay further theoretical and experimental investigation. In particular, the mechanics of the behaviour of the dense phase in a bubbling bed are not understood in detail. It is known that the shape and velocity of rise of bubbles are influenced by the physical nature of the fluidized particles. For example, X-ray experiments have shown that bubbles in a bed of irregularly shaped particles, such as sand, have smaller wakes and rise at greater velocities than bubbles in similar, but spherical, material. Also, the size of the bubble wake region increases as the particle size of the fluidized material is decreased. Bubbles in low density spherical material of very small particle size, for example, 50µ diameter, have large wakes so that their shape approaches the characteristic spherical cap form observed for large air bubbles in water. In Fig. 4 the difference in shape between bubbles produced in coarse coal and in a fine catalyst can be seen. In addition, the movement of a bubble through a bed of fine material can generate eddies within the dense phase and this enhances the mixing of particles. This very liquid-like behaviour is entirely absent from beds of coarser particles.

Such observations as these immediately suggest that there is interference, or contact, between neighbouring particles. Generally the voidage of the dense phase is about 0.4: this means that, even if the particles are ideally arranged in the most open form of packing, rhombohedral, the separation between particles is only about one-sixteenth of a particle diameter. As a bubble rises the dense phase flows around it and there is a relative motion between adjacent particle layers around the bubble. Because of the close packing of the particles it is reasonable to expect that there is interference between neighbouring particles close to the bubble during this shearing movement. The formation of the particle wake, and the solids circulation therein, may even be consequences of this particle interference.

Striking evidence in support of the existence of interparticle contacts, but not necessarily in support of the explanation advanced above, is the well established fact that a fluidized bed of conducting particles exhibits a significant overall electrical conductivity. Both liquid and gas fluidized beds behave in this manner. property has been exploited to heat gas fluidized beds of carbon particles by resistance heating in such processes as the manufacture of acetylene. Liquid fluidized beds of conducting particles have also been suggested for use where high surface area electrodes are needed. Until the mechanism of the conductivity is known, optimization of the design and operation of such beds will be entirely a matter of trial and error.

The evidence in support of the existence of interparticle contacts, and particularly this last observation of the electrical conductivity of a bed, is sometimes cited in order to attempt to invalidate the gas flow theories of Davidson, Murray and Jackson because these neglect the effects of any such contacts. The attempted argument does not necessarily follow. Interparticle contacts could occur without significantly affecting the gas flow pattern, and the striking agreement between observation and the predictions of Jackson and of Murray shows that it is valid to neglect interparticle forces when dealing with this aspect of the behaviour of bubbles. But they must be taken into account when considering the detailed

mechanics of the dense phase.

To sum up, experiments have now given a good understanding of the type of flow patterns obtained inside fluidized beds. Mathematical models have enabled some of the behaviour of gas bubbles in gas fluidized beds to be predicted, but much knowledge important to the better design and optimization of such beds is still required. One disturbing feature is that attempts to produce better models have produced mathematical equations that are insoluble and it seems that more experimental information on the fundamental properties of the dense phase is needed. The latest models were discussed at a recent conference at Eindhoven, but there were no signs of an imminent "break through" in this field.

Some New Behaviour-disrupting Amphetamines and their Significance

by

J. R. SMYTHIES V. S. JOHNSTON R. J. BRADLEY

Department of Psychiatry, University of Edinburgh

F. BENINGTON R. D. MORIN L. C. CLARK, jun.

Department of Psychiatry and Surgery, Medical College of Alabama, Birmingham, Alabama The effect of a series of amphetamines has been investigated, and the results suggest that substitution in the para-position is important for hallucinogenic properties.

AMPHETAMINE is the paradigm of a central stimulant drug, and it is also known to cause a paranoid psychosis closely resembling a schizophrenic illness in certain addicts. Peretz et al.1 first reported that a derivative of amphetamine-3,4,5-trimethoxy amphetamine—was hallucinogenic in man. Its effects were very similar to those of its close chemical relative mescaline. Smythies et al.2 have developed a behavioural test for animals, based on the Sidman Avoidance Schedule and the Bovet-Gatti profiles, which has proved to be reliably predictive of the hallucinogenic effect of a drug on man. We used this test to show that of the nineteen possible methoxylated phenylethylamines, only three were active in disrupting behaviour—the 3,4,5 compound (mescaline itself), the compounds 2,3,4,5 and 2,3,4,5,6, in order of increased activity. All the other 16 were inactive. Thus it appears that for hallucinogenic activity, at least 3 methoxy groups are required, and that these had to be in the 3,4,5 configuration. The two other active compounds were more lipid-soluble than mescaline, and are not metabolized by amine oxidase; mescaline being metabolized by diamine oxidase but not by monoamine oxidase.

In this present investigation, we have examined the following series of methoxylated phenylisopropylamines (amphetamines): the 3,4,5, 2,4,5. 2,4,6 and 2,3,4 trimethoxy compounds; the 2,3, 2,5, 3,5 and 3,4 dimethoxy compounds; and the 3 monomethoxy derivatives 2, 3, 4. Each compound was tested on two animals exactly as described in our previous communication². The results in this series were quite different from those in the ethylamine series.

In the trimethoxy amphetamines activity was in decreasing order: $2,4,5 > 3,4,5 > 2,4,6 \gg 2,3,4$. A typical Bovet-Gatti hallucinogenic profile was obtained for the first three, whereas the 2,3,4 compound was almost inactive. A very similar result was obtained in human studies by Shulgin³, who found the 2,4,5 compound to be seventeen times as active a hallucinogen as mescaline, the 3,4,5 compound to be approximately twice as active, and the 2,3,4 compound to be inactive.

In the dimethoxy series, we found the 2,3, 2,5 and 3,5 compounds to be inactive, but the 3,4 compound was highly active, 12.5 mg/kg being roughly equivalent to 25 mg/kg mescaline.

The monomethoxy series was the most interesting. The ortho-compound showed moderate amphetamine-like activity over a wide dose range.

Para-methoxy amphetamine (PMA), however, proved the most potent hallucinogen we have so far tested (with the exception of LSD). In a dose of 3·1 mg/kg, it produced a typical "low dose hallucinogenic" Bovet-Gatti profile, quite distinct from the Bovet-Gatti profile for amphetamine. In doses of 6·2 mg/kg, it disrupted bar-pressing behaviour completely, and induced bizarre behaviour in both the rats tested. Although the rat could walk about normally, and appeared to be able to eat and drink normally.

mally, it frequently walked backwards—a typical mescaline effect. It would show exaggerated startled responses in the absence of external stimuli and would frequently engage in strange behaviour reminiscent of shadow boxing—rearing and pawing in the air. If placed on a table, it would walk apparently normally towards the edge and fall off, and would do this repeatedly if replaced on the table. This period of abnormal behaviour lasted one day in one rat, when the animal died, and one week in the second rat, when this animal also died.

Thus the present data would suggest that the essential feature of the "hallucinogenic" molecule in this series is the para-methoxy group. All compounds lacking this were inactive and compounds with additional groups were variously weaker. The different results in the phenylethylamine series may be due to the fact that the apparently inactive compounds may be too easily oxidized by amine oxidase to produce behavioural effects following parenteral injection. It is known that the 3,4-dimethoxyphenylethylamine is a much better substrate for amine oxidase than is mescaline^{4,9}. Once the molecule is protected from amine oxidase by α-methylation, then the behavioural reaction to the drug, injected parenterally, may more truly reflect activity at the site of action. To test this hypothesis, we pretreated an animal with 50 mg/kg iproniazid 3 h before injecting 6.2 mg/kg of para-methoxyphenylethylamine (PMPEA)—which is also o-methyl paratyramine. Neither of these given alone produced the slightest effect on behaviour, but when they were given together. behaviour was completely disrupted and toxic effects rapidly appeared: the rat lay on its side twitching slightly, and died in a few hours. The same dose of iproniazid given before injecting 12.5 mg/kg mescaline increased the effect of mescaline only two-fold and no toxic effects appeared. This experiment is being repeated with lower dosages of PMPEA. This increase in the toxicity of 4-methoxyphenylethylamine following MAO has also been reported to produce an intense rage reaction and hyperthermia in cats10. It has also been found that paramethoxy amphetamine at 25 mg/kg was lethal in cats after producing a similar rage reaction.

The severe and prolonged disruption of behaviour produced by PMA suggests an irreversible inhibition of an enzyme—possibly catechol o-methyl transferase. Because 3-methoxylation is the normal method of inactivating catechol amines, it seems not impossible that catechol o-methyl transferase might be blocked, or its action distorted in some way, by 4-methoxylated phenylethylamines or isopropylamines. A second hypothesis is that because amphetamine is usually para-hydroxylated in the rat, the interference with this reaction by the para-methoxy group might have behavioural results.

Thus it would be of interest to analyse by biochemical and pharmacological techniques the mechanisms of action of PMA. The action of PMA on species that do and do not parahydroxylate amphetamine would also be of interest. Human testing with PMA would clearly require great care. The potent and long lasting hallucinogen STP has been identified as a derivative of dimethoxy amphetamine.

Finally, these findings suggest the hypothesis that schizophrenia may be associated with 4-methoxylation of catecholamines or of tyramine, or with some disturbance in whatever biochemical mechanism is affected by these paramethoxylated compounds. In this respect, the recent reports by Boulton et al.7, that one "pink spot" excreted by schizophrenics is paratyramine, and by Jenner et al.*, that a manic depressive patient was excreting very large amounts of paratyramine metabolites, are of interest. Our data suggest: (1) that o-methyl paratyramine produced in the synapse (separated from MAO) would have profound and long lasting effects on behaviour, and that the fact that 3,4-dimethoxyphenylethylamine (DMPEA) is inactive in humans on parenteral injection may be due to its rapid breakdown by MAO, and that it also might disrupt behaviour if locally produced in the synapse; and (2) that the psychosis found in amphetamine addiction may be associated with the production of 4-methoxy amphetamine

Inertial Confinement of Extended Radio Sources

by DAVID S. DeYOUNG Center for Radiophysics and Space Research, Cornell University, Ithaca, New York

W. I. AXFORD Departments of Physics and Applied Electrophysics, University of California, San Diego, La Jolla, California

The confinement of extended radio sources may be a dynamic rather than a static process where the internal pressure of the source is balanced by the ram pressure of the intergalactic gas.

In this article, we discuss the nature of those strong radio sources in which the radio emitting regions are separated from the parent object by distances comparable with or greater than the dimensions of the sources. These radio sources are often double, with the parent object (commonly a giant elliptical galaxy) situated between the sources and roughly at their centroid. Descriptions of such sources, of which Cygnus A is a well known example, have been given by Maltby, Matthews and Moffet1 and by Burbidge, Burbidge and Sandage².

Apart from information concerning the radio spectra, present observations of strong radio sources provide little more than the luminosities and approximate dimensions of the components, although with higher resolution studies now becoming possible it seems that a certain amount of fine structure can be observed. In the case of Cygnus Athe emitted power in the radio frequency range is estimated to be 4.4 × 1044 ergs/sec, with the two (approximately equal) components separated by about 79 kparsec and having diameters of about 35 kparsec. From such information the usual procedure is to estimate the minimum total energy, E_{min} , in particles and the magnetic field required to produce the observed luminosity by the synchrotron mechanism. Thus, for Cygnus A, if the energy densities of relativistic electrons and nuclei are equal, and if the magnetic field fills the emitting volume uniformly, the minimum energy is of the order of 3×10^{59} ergs, and the corresponding magnetic field strength, H_0 , is about 7×10^{-5} oersted^{1,2}. If the magnetic field fills only a fraction, f, of the volume of the source, then the energy required decreases by a factor $f^{3/7}$ and the magnetic field increases by a factor $f^{-2/7}$; for example, if $f = 10^{-2}$, then $E_{min} \approx 2 \times 10^{66}$ ergs and $H_0 \approx 3 \times 10^{-4}$ oersted. For sources other than Cygnus A, similar calculations imply

 $E_{min} \approx 10^{67} - 10^{61}$ ergs and $H_0 \approx 10^{-6} - 10^{-4}$ oersted. The significance of these calculations is limited by their over-simplification of the problem. Nevertheless, an important result is implied, namely, that the internal pres-

sure of the emitting region is at least $H_0^2/8\pi$. The actual pressure might exceed this value considerably, for a comparable pressure must be exerted by the energetic particles involved, and the configuration need not correspond to the minimum energy configuration for the observed luminosity. One would also expect the emitting regions to be roughly in hydrostatic equilibrium in a co-moving frame of reference so that regions of high magnetic pressure tend to have low particle pressure and vice versa. To maintain the pressure within such an object (hereafter called a "plasmon", a term introduced in a slightly different sense by Shklovskii⁸) which is well separated from its source and presumably in near equilibrium with its surroundings, an external confining pressure of at least $H_0^2/8\pi$ is necessary.

It has been suggested that the confinement could be provided by an intergalactic magnetic field, and that such a field would also produce the observed alignment of the plasmons with the object from which they have been ejected4. This would require an intergalactic field strength at least equal to the minimum value of H_0 required for any observed source of the type under discussion. That is, the intergalactic field would have to have a strength $H_m \ge 7 \times 10^{-5}$ oersted, as deduced for Cygnus A. pressure exerted by the intergalactic magnetic field, however, should not exceed the total pressure of the interstellar medium in our own galaxy, which implies that H_m is less than about 1×10^{-5} oersted. This is probably a gross overestimate of H_m (ref. 5), but it is none the less far too small to confine and collimate the Cygnus A plasmons. Moreover, if the intergalactic field were the confining agency, the pressure inside all similar objects would be the same (that is, $H_{m^2}/8\pi$), and there is no reason to believe that this is the case.

With essentially the same arguments, one is led to reject the possibility that the confinement is due to the static pressure of the intergalactic gas in a "hot" universe. a conclusion which is also implied by observations of the

X-ray background⁵. The only alternative seems to be that the confinement is essentially dynamic rather than static, with the internal pressure of the plasmons being balanced by the ram pressure of the intergalactic gas. $\rho_0 v^2 \approx H_0^2/8\pi$, where ρ_0 is the density of the intergalactic gas and v is the current speed of the plasmon. Note that this requires only that the intergalactic gas should be sufficiently dense and makes no demands on the pressure of this gas or the intergalactic magnetic field strength, both of which could be quite low. In addition, the internal pressure of the plasmons can vary, for the ram pressure depends on the speed of the plasmon, a quantity which does not have to be the same in all cases and which may vary in time for any one case. The collimation of plasmons with the parent object cannot be due to the intergalactic magnetic field in these circumstances, but must result from a directed ejection, presumably controlled by the distribution of matter in the parent object.

Perhaps the most interesting aspect of this suggestion is that it permits us to deduce a rough lower limit for the density of the intergalactic medium. Taking $v \approx 3 \times 10^{10}$ cm/sec and $H_0 \approx 7 \times 10^{-5}$ oersted (as required for Cygnus A), we then find $\rho_0 \geq 2 \times 10^{-31}$ g/cm³. There is a slight uncertainty caused by the possibility that relativistic effects might be important; however, we do not consider this likely. It seems more probable that the internal pressure of the Cygnus A plasmons is much larger than the minimum value we have assumed, and that v is somewhat smaller than the speed of light. Thus the actual value of ρ_0 is probably substantially larger than 2×10^{-31} g/cm³, at least in clusters of galaxies. This argument is not without flaws, but we believe that it is useful, because this is probably the only case in which we can be reasonably sure that we are observing a direct interaction involving the intergalactic medium. That is, the strong radio sources provide the best available intergalactic probes.

If these arguments are inverted so that a lower limit is obtained for v, then they provide a counter to the suggestion that the plasmons which constitute the radio sources such as Cygnus A are gravitationally bound to the parent object³. If the plasmon is confined by ram pressure alone, then taking an upper limit of ρ_0 to be 10^{-27} g/cm³, we find that $v \ge 4 \times 10^8$ cm/sec with $H_0 = 7 \times 10^{-5}$ oersted, which is well above the escape speed for even a very large galaxy. If ρ_0 is taken equal to the "cosmological" value of 2×10^{-29} g/cm³, then $v \ge 3 \times 10^9$ cm/sec. This suggests that the Cygnus A plasmons must be moving at speeds as nearly as great as the speed of light and hence that their age is only 10^5 – 10^6 years.

These arguments refer only to the maximum ram pressure of the intergalactic gas. This is attained in the vicinity of stagnation points on the interface between the plasmon and the impinging intergalactic gas. Because the normal pressure can drop to quite low values elsewhere on the interface, it is not immediately clear that confinement of the plasmon can be produced by ram pressure effects alone. It is not possible to give a completely general treatment of this problem, allowing for arbitrary distributions of magnetic field and plasma within

the moving cloud, but we have been able to construct a simple model which illustrates how the confinement occurs. First, note that as a result of the drag exerted by the intergalactic gas the plasmon must be decelerating, so that in a co-moving frame there is an effective gravitational field directed parallel to the direction of motion of the plasmon. Consider a quasi-equilibrium situation in which this gravitational field is essentially uniform throughout the plasmon and produces an acceleration $(-a\hat{z})$ cm/sec², where the z axis is directed back along the trajectory of the plasmon and z=0 at the stagnation point. Let the combined particle and magnetic energy in the plasmon be & per unit mass at each point, and further assume that ε has the same value throughout the cloud. The total pressure distribution within the plasmon consequently obeys the simple hydrostatic law $p = p_0$ exp (-z/h), where $h = \varepsilon/a$ is an effective scale height. The Newtonian approximation for hypersonic flow is appropriate in this situation, and hence the external pressure acting normally on the surface of the plasmon is $\rho_0 v^2$ $\cos^2 \xi$, where ξ is the angle between the incident flow direction and the outward normal to the surface (Fig. 1). The shape of the plasmon (which is axisymmetric) is obtained by equating the external and internal pressures

$$p_0 e^{-z/h} = \rho_0 v^2 \cos^2 \xi \tag{1}$$

Thus

$$r = 2h \tan^{-1} \left[e^{z/h} - 1 \right]^{1/2} \tag{2}$$

with the maximum radius of the plasmon being πh . The

calculated shape is shown in Fig. 1.

We emphasize that this model calculation is designed only to illustrate the general principles of inertial confinement of a plasmon, and not necessarily to give an accurate representation of any particular strong radio source. Nevertheless, it does provide good qualitative agreement with observations for the general shape of the radio sources. It should be noted that any intergalactic magnetic field which exists tends to be compressed and hence amplified at the surface of the moving plasmon, similar to the case of the interplanetary magnetic field at the surface of the magnetosphere. Instabilities of this surface would tend to mix filaments of strong field with energetic particles from the interior, thus giving rise to synchrotron radiation in addition to that resulting from the internal magnetic field of the source.

If we accept this estimate for the maximum crosssection of the plasmon, then the drag due to the intergalactic gas is roughly $\pi^3 h^2 \rho_0 v^2 = Ma$, where M is the total mass of the plasmon. Because $a = \mathrm{d}v/\mathrm{d}t$ and $h = \varepsilon/a$, this can be regarded as a differential equation for the motion of the plasmon which integrates to give

$$v = \left[v_0^{1/3} - \frac{1}{3} K^{1/3} t\right]^3 \tag{3}$$

where v_0 is the initial speed and $K=(\pi^3\epsilon^2\,\rho_0/M)$. The time required to stop the cloud is $t_s=3(v_0/K)^{1/3}$. For the case of Cygnus A, if we take $Mv^2/2=\epsilon M=E_{min},\,f=10^{-2},$ and $v_0=3\times 10^{10}$ cm/sec, then $M=2\times 10^6 M_{\odot},\ \rho_0\geqslant 4\times 10^{-30}$ g/cm³, and $t_s\leq 2\times 10^5$ years. This is comparable with the

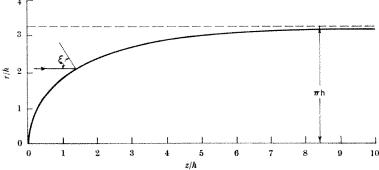

Fig. 1. Calculated shape of plasmon.

present age of the object, suggesting that the deceleration might be quite severe. In its present state Cygnus Acould continue to radiate for 3×10^7 years or more, which is much longer than ts. The plasmon does not radiate significantly, however, after it halts, because as it decelerates it expands, and the resulting adiabatic cooling of the plasma together with the reduction of H_0 quenches the effectiveness of the synchrotron mechanism. This could explain why the components of double radio sources are not seen to be separated by more than about 200

kparsec from the parent object.

We are severely hampered in pursuing theories of this type by a lack of knowledge of physical conditions in the radio sources. In particular we would like to know the quantities f and H_0 in a source such as Cygnus A. These could in principle be found by radio observations with sufficiently high resolution (which would yield an estimate of f), and from X-ray observations. If the X-rays emitted by Cygnus A result from inverse Compton scattering of the cosmic black body radiation by the energetic electrons in the source, then the ratio of the X-ray and radio luminosities is roughly $8\pi W f H_0^2$, where $W \approx 1.6 \times 10^{-12}$ is the energy density of the black body radiation. According to our previous estimates for fHo2 in Cygnus A, the X-ray luminosity should be approximately 4×10^{42} ergs/ sec (if f=1) or 2×10^{43} ergs/sec ($f=10^{-2}$); both figures are below the present observational limits?

Our attention has been directed to a recent paper by Ryle and Longair⁸ which is relevant to the present work. On the basis of a simple kinematical model, Ryle and Longair have shown that one can deduce the age and current speed of the plasmons as well as some information about their deceleration and rate of change of luminosity. By combining these results with our arguments on the dynamics of plasmons one should be able to reduce the number of free parameters quite substantially, bearing in mind, however, the limitations imposed by the assumptions involved.

Infrasonic Pressure Waves from the Aurora: a Shock Wave Model

by CHARLES R. WILSON Geophysical Institute, University of Alaska

The anisotropic radiation of infrasonic waves from moving aurorae is explained by a shock wave model. The acoustic waves, as observed on the ground at a site ahead of the moving aurora, are amplified in the direction parallel to the auroral motion by superposition of wave fronts if the auroral form is moving at supersonic speed.

DURING periods of great geomagnetic activity, infrasonic waves with an amplitude of a few dynes/cm2 and with periods from 40 to 80 sec have been observed at low latitude stations to come from a source in the polar regions. The times of occurrence and azimuths of arrival of the travelling pressure waves indicated a source near the local time region of maximum activity in the auroral Recent observations of infrasonic associated with auroral activity made in the auroral zone at the Geophysical Institute at College, Alaska, show that travelling pressure waves are radiated when large scale auroral forms move with supersonic speed2.

The association of auroral infrasonic waves with high speed auroral motions resulted from direct observations of infrasonic signals from visible aurorae as well as from statistical studies. The local midnight reversal in the direction of auroral motions during a typical auroral sub-storm³ corresponds to the statistical reversal at local midnight in the azimuths of arrival of auroral infrasonic waves from east of the magnetic meridian to west of this direction. This observed simultaneous reversal of auroral motions and azimuths of incoming infrasonic waves implies that the auroral infrasonic waves are radiated principally in a direction parallel to the motion of the auroral forms.

An example is given in Fig. 1 to show the relation between the direction of motion of a supersonic auroral form and the direction of the observed infrasonic wave which was generated by the moving aurora. The successive positions, at intervals of 1 min, of the auroral arc are projected from the 100 km level onto a map of Alaska in Fig. 1 showing that the infrasonic wave, indicated by the

long arrows, was radiated in a direction parallel to the motion of the arc.

The infrasonic wave from this moving are is shown in Fig. 2 with several other examples, as the superposed pressure versus time traces from four microbarographs with the time scales shifted to give waveform alignment for these coherent waves. At 0613 h local time, just 7 min after the arc passed over the observing station at College, Alaska, the infrasonic signal arrived from an azimuth of 304° from an elevation angle of about 60°. All the

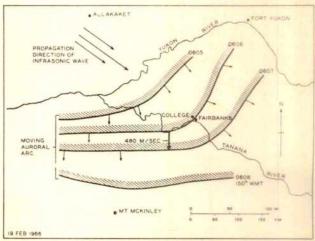

Fig. 1. Projection of a fast moving auroral arc, at one minute intervals on a map of Alaska with the direction of the associated infrasonic wave.

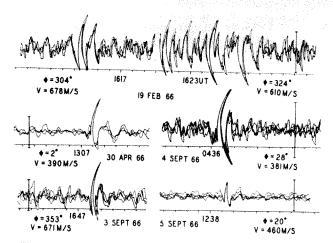

Fig. 2. Superposed pressure versus time traces of four microbarographs for infrasonic waves observed in the auroral zone. Time scale is in minutes and vertical bars represent 5 dynes/cm² pressure change.

examples found by Wilson and Nichparenko² of infrasonic waves generated by aurorae showed that only aurorae moving with supersonic speed produce infrasonic waves. This fact strongly suggests a shock wave mechanism for generating auroral infrasonic waves.

A typical shock wave pressure versus time profile does occur for many of the observed auroral infrasonic waves. Several examples of these are shown in Fig. 2 on April 30 and September 3, 4 and 5, 1966, in which a positive pressure spike is followed by a longer negative phase. The more complex waveforms, such as that shown in Fig. 2 at 1625 UT February 19, are thought to be due to multiple path propagation effects, the complex geometry of the emitting auroral forms, or superposition of signals from several sources. Continuous sinusoidal waveforms such as those resulting from a harmonic source are never observed in auroral infrasonic waves.

Any model for the generation of infrasonic waves by moving aurorae must explain the following three principal characteristics: the pressure wave is radiated highly anisotropically in the direction of the auroral motion; detectable acoustic energy is radiated only if the motion of the form is supersonic; and the waveform is like that of a shock wave and not sinusoidal.

A model that will produce the observed characteristics of auroral infrasonic waves is described here. In Fig. 3 an auroral form is shown moving from right to left parallel to the surface of the Earth, with a speed v. If the auroral form produces an acoustic pulse of constant phase as it passes through each interval of path Δx_{η} , then the moving auroral form will produce an acoustic shock if v is greater than c, the speed of sound. The shock front will propagate to the ground with a speed c as shown in Fig. 3 where $\theta = \arcsin c/v$. In this model, c is taken to be constant at

all heights and the radiation of the acoustic pulse from each interval Δx_{η} is assumed to be isotropic. The first acoustic energy in the shock arrives at P from the interval shown in Fig. 3 as Δx_0 along the ray path R_0 , where R_0 is normal to the shock front. The delay time for the arrival of this initial acoustic energy from the interval Δx_0 is given by $t_0 = R_0/c = h/c \ (1-(c/v)^2)^{-\frac{1}{2}}$. Although the emission of acoustic energy by the aurora is continuous as it moves, it is useful to describe the process by a numerical approach. The path along x is divided up into finite intervals Δx_{η} and an amount of energy $U \Delta x_{\eta}$ is emitted within each interval where U is the acoustic energy emitted per unit path length by the moving aurora.

The amplitude of the acoustic shock received at the ground point P at any instant of time is the scalar sum of the acoustic pulses radiated isotropically from each interval Δx_{η} . The pressure versus time profile of the shock received at a point P will depend on the shape of the acoustic pulse emitted by the aurora in each interval Δx_{η} , the delay time of each pulse, and on the degree of attenuation of each pulse.

In order to make the numerical integration to find the profile of the shock at P, Fig. 4 was constructed to show the calculated delay time of each acoustic pulse from each interval Δx_n at the instant of time when the shock front has just reached the point P. The x co-ordinate x_n of each interval of path length Δx_{η} is plotted along the ordinate in km. The origin of x is at the zenith over P and x increases toward the right in Fig. 3. The delay time for the pulse from each interval Δx_{η} , measured in seconds along the abscissa in Fig. 4, is the time for propagation of each acoustic pulse from its position in space at the time t_0 to the point P. Thus the delay time for the pulse from the interval Δx_0 is zero; the delay time for the pulse from the interval at x=0 is 45 sec and for the pulse from $x_{\eta} = 100$ km is 18 sec as shown in Fig. 4. If it is assumed that the acoustic pulse from each interval Δx_{η} has a 20 sec period with symmetrical positive and negative phases, as shown in Fig. 4, and that geometrical attenuation occurs, then a numerical sum of the pulses emitted along the path of the aurora from x = 180 km to -40 kmgives the shock pulse shown in Fig. 4. From this figure it can be seen that there is no significant contribution of acoustic energy to the shock pulse from acoustic pulses in intervals for which the delay times are greater than about 40 sec. The x co-ordinates for the Δx_n intervals for which the acoustic pulses have a delay time of 40 see are 130 km and about 2 km. Thus, for this example in which v=2c, the shock energy received at P due to the motion of the auroral acoustic source comes from the region of path from 130 km away to about overhead. Thus the supersonic motion of the source of the auroral acoustic pulse toward the zenith of the observing site at P causes the generation of a shock pulse radiated in the forward direction by the superposition of the infrasound emitted from each interval Δx_{η} of the auroral path. The

the highly directional properties of the radiation of infrasound in the forward direction with respect to the supersonic aurora.

To determine how much the actual sound propagation would deviate from that assumed for c constant at all heights a ray tracing calculation was carried out using a standard sound velocity profile for the atmosphere with an isotropic source of sound radiating at the 100 km level. The ray paths for each 10° of initial propagation direction are shown in Fig. 5. The deviation of the actual wavefront from a spherical wavefront which would result if c were constant at all heights is shown in Fig. 5 by the relative position of the short bars on the rays for 10°-60° with respect to the solid circle which represents a section of the spherical wavefront. Only for nadir angles greater than 50° is there a significant deviation due to the actual sound profile in the lower atmosphere. Now from the model we find that there was significant contribution to the shock pulse only for intervals from overhead out to about 130 km. Thus for the range of x_n which is important the nadir angles are less than 50°. The approximation of constant sound velocity used in the model is therefore sufficiently good.

Sound that is radiated at the 100 km level in directions that are within 30° of the horizontal, as indicated by the 60° cone in Fig. 5, will propagate within the mesospheric sound channel. That radiated within 60° of the zenith will either be absorbed at higher altitudes or refracted back to the Earth to produce weak secondary signals.

The model predicts that the delay time for propagation along the path R_0 will be shorter for higher velocity auroral forms and that the horizontal trace velocity of the shock

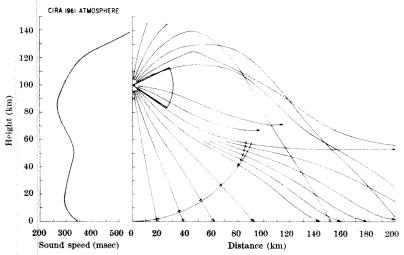

Fig. 5. Sound velocity profile and ray tracing diagram for an isotropic source at 100 km level.

amplification of the shock pulse can be seen in Fig. 4 to be a factor of about 10 greater than that which would be received from a single acoustic pulse from the radiation in one interval. The piling up of the wave packets from "upstream", x > 0, relative to the spreading out of those from "downstream", x < 0, can be seen in Fig. 3, in which the positions in space of the spherical wavefronts from each interval Δx_{η} are plotted as short bars for the instant of time t_0 . Thus the acoustic pulses from intervals for which $x_n > 0$ are all close together so that their superposition at P causes the shock pulse to build up in the forward direction. Now from Fig. 4 it can also be seen that if an aurora started at x=0 and moved away from P in the negative x direction, and it the difference in the delay time between successive pulses was greater than the pulse width, then no constructive superposition would occur.

This model is able to explain the shock wave like character of individual auroral infrasonic waves: the amplification of the basic auroral acoustic emission and

wave will be equal to the velocity of the auroral form. The model requires that, in the frame of reference moving with the aurora, the acoustic pulse generated in the aurora has a constant shape and phase. This would be true for either the mechanism of heating by auroral electrons suggested by Maeda and Watanabe or for that of electrodynamic drift suggested by Piddington⁵ for the generation of the initial acoustic energy in the aurora itself for conditions of constant auroral electron flux. The observations of auroral infrasonic waves made in the auroral zone are consistent with this shock wave model3.

DNA Synthesis and DNA Content of Leucocytes in Acute Leukaemia

by MINOU D. FOADI E. H. COOPER R. M. HARDISTY

Department of Haematology, Institute of Child Health and Hospital for Sick Children, Great Ormond Street, London, WCI, and Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London, SW3

Inhibition of division of blast cells is common in untreated acute leukaemia of childhood. During relapse, while a patient is on maintenance therapy, the proportion of blast cells in cyclic division

THE labelling of blast cells in acute leukaemia with tritiated thymidine (3H-TdR) in vitro1,2 and in vivo2,3 has shown that only a small proportion of these cells is engaged in DNA synthesis at any given time. There are strong indications that only part of the leukaemic cell population is engaged in cyclic division, and it has been suggested that the cells eventually mature into sterile blasts which do not divide2, although some of these cells could be a mitotically dormant reserve. The work of Mauer and Fisher³ has indicated that the generation time of the blast cells in untreated acute leukaemia of children may be as short at 15-20 h.

A short pulse labelling with 3H-TdR can provide information about the percentage of cells in DNA synthesis, and quantitative cytochemical determination of the DNA content combined with the labelling can give the relative distribution of the cells in the various compartments of interphase activity^{4,5}. This approach has been applied to the analysis of populations of blast cells in leukaemic children in two phases of the disease: in the untreated acute state and at the onset of relapse after a period of

Sixteen children suffering from acute leukaemia were first studied before treatment was started. Fourteen examinations were performed on eleven patients in an early phase of relapse; in eleven instances the patient was on chemotherapy at the time of investigation. The bone marrow was examined every 8 weeks and occasionally at other times. When blast cells formed more than 10 per cent of the total nucleated cells in the marrow or were present in the peripheral blood, the patient was considered to be in relapse.

The methods used for the identification of the cells, analysis of DNA content, *H-TdR labelling and measurement of cell size have been described in detail elsewhere⁵⁻². Some of the marrows were incubated with Some of the marrows were incubated with 5 $\mu c.$ of tritiated uridine (*H-UR, specific activity = 5 c./mmole) for 1 h; incorporation of the 3H-UR was

studied by autoradiography.

The percentage of blasts synthesizing DNA (labelling index) in the bone marrows of fourteen cases of acute lymphoblastic leukaemia before treatment varied from $0 \cdot 1 - 10 \cdot 2$; in the peripheral blood taken at the same time the labelling index was 0·1-7·2. The ratio of the labelling index in the bone marrow to that in the blood was 0.8:1 to 7.0:1. A similar relationship has been reported previously^{1,2}. A very low peripheral blood labelling index was seen in one patient with a high blast cell count (900,000/mm³) and in another with only 135 blasts/mm³. A case of acute myelomonoblastic leukaemia had a labelling index of 10.2 in the bone marrow and 7.7 in the peripheral blood, and one of acute myeloblastic leukaemia had a labelling index of 7.5 in the bone marrow and 5.5 in the blood. .

The distribution patterns for the DNA content of the cell populations were similar; most of the cells had DNA contents close to the normal diploid amount. Post-DNAsynthetic, premitotic (G_2) cells with 4n DNA contents formed less than I per cent of the population. A few unlabelled cells had DNA contents between the 2n and 4n modes; these may have represented an uploid cells of atypical DNA content. Estimation of the DNA content by measurement of Feulgen dye absorbance cannot detect the small differences associated with increase or decrease of one or two chromosomes. Chromosome analyses were made on seven of these cases, six of which were normal. In this series no marked aneuploidy was encountered; others have reported that normal chromosome numbers are present in about 50 per cent of cases of acute leukaemia*. In the case of acute myeloblastic leukaemia it was possible to identify myeloblasts and myelocytes, although the latter were morphologically abnormal. The DNA distribution pattern of these two cell types indicated that a hold-up at the 2n mode occurred at both stages of differentiation.

Figs. 1a and b show the relation of DNA content, 3H -TdR labelling and cell size in two cases of acute lymphoblastic leukaemia. In one of them (Fig. 1a), there was evidence of a bimodal population in the size distribution of the 2n cells; in other cases, however, this bimodality was absent (Fig. 1b). It would seem therefore that size alone is unlikely to be a sound criterion for distinguishing cells in G_1 which are actively proliferating, as opposed to those which are no longer participating in regular cyclic division. In some of the patients there was evidence of considerable cell growth as the blast cells moved through the cell cycle, but in other cases this was not particularly marked. Autoradiographs of cells incubated with 3H-UR were exposed for 4 weeks, at which time 78-98 per cent of the blasts were labelled, the intensity of labelling tending to be greater in the large cells. Some of these large cells were only weakly labelled, however, and some of the smallest cells were highly labelled, which points to a non-uniformity of metabolic activity independent of the cell size. Furthermore, aneuploid cells out of cycle may be large and confuse the picture.

The overall rates of DNA synthesis, as indicated by ³H-TdR grain counts, were measured in those cases in which there were sufficient normal cells in the preparations. No significant difference was detected between the acute

lymphoblastic leukaemic and normal cells.

During the response of the cases of acute lymphoblastic leukaemia to chemotherapy with 6-mercaptopurine and prednisone, or vincristine and prednisone, the total numbers of blasts and of labelled cells in the peripheral blood fell rapidly, and there was a progressive decline in the percentage of blast cells synthesizing DNA. There was no apparent relation between the initial labelling

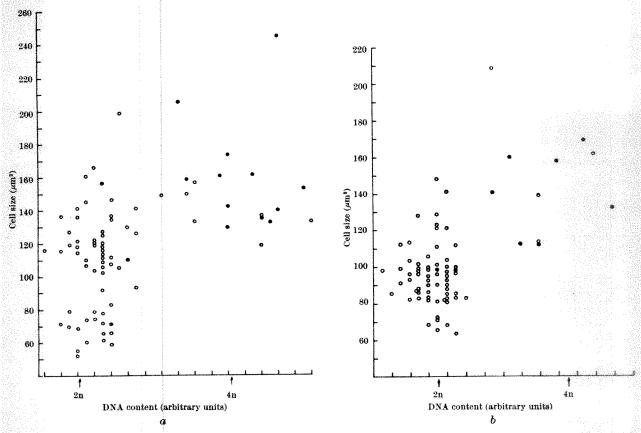

Fig. 1. Relation between cell size, DNA content and DNA synthetic activity in lymphoblasts in the bone marrow of two patients (a) and (b) with untreated acute leukaemia. •, Lymphoblasts synthesizing *H-TdR; O, lymphoblasts not synthesizing *H-TdR.

index in bone marrow or blood and the clinical course of the leukaemia.

It is clear that the labelling index was frequently higher in relapse than on first presentation (Table 1). The chromosome analyses and the estimations of the DNA content of the interphase cells indicated that there was a higher incidence of aneuploid cells in relapse than in the untreated cases. Fig. 2 shows the distribution patterns of the DNA content of the cells from two patients in relapse; there was a reduction in the percentage of cells at the 2n mode and the appearance of more unlabelled cells between the 2n and 4n modes, indicating an increase in the frequency of aneuploid cells. The distribution was similar to that seen in a blast cell crisis in chronic myeloid leukaemia4. The distribution of DNA contents of the DNA-synthesizing cells of the patients treated with methotrexate indicated that the high labelling index could not be caused by the release of the methotrexate block by the 3 H-TdR; such a release is associated with the formation of a synchronous wave of DNA synthesis, so that after 30 min most of the cells synthesizing DNA would be expected to be near the 2n mode. Evidence of a hold-up at G_{2} was observed in some patients treated with cyclophosphamide. This type of block has been reported in several types of cell systems following treatment with alkylating agents 9,10 .

At the first examination of a patient with a tetraploid acute lymphoblastic leukaemia, who had relapsed for the first time 7.5 years after the original diagnosis, following a long unmaintained remission, 17 per cent of the blasts in the peripheral blood were synthesizing DNA: bone marrow was not obtainable at this time. The leukaemic cells remained tetraploid until the patient's death 6 months later and no alteration of the modal DNA content was observed during the response and subsequent relapse on chemotherapy. The 3H-TdR grain counts were

approximately twice that of the normal cells (acute lymphoblastic leukaemia blasts, mean grain count = 73, myelocytes, mean grain count = 31); this is comparable with the relative 3H-TdR grain counts over the diploid and tetraploid cell lines in regenerating liver 11. Fig. 3 shows the DNA distribution in this patient.

This investigation confirms that the cell population in untreated acute leukaemia has a low labelling index and a large proportion of the cells with DNA contents close to the 2n mode. The pattern of cell behaviour does not remain constant, however, when the evolution of leukaemia is modified by chemotherapy; a far higher proportion of the population may be committed to division during a relapse while on maintenance therapy. This indicates that the "maturation" of the leukaemic blast cell to form a non-dividing blast is not a constant feature of the disease and may be affected by the overall rate of expansion of the cell population. It is unlikely that the change in the population can be explained on the grounds that the non-dividing blasts are more susceptible to chemotherapy than the leukaemic

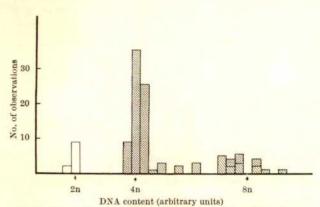

Fig. 3. Distribution of nuclear DNA content of tetraploid leukaemic cells in peripheral blood. White columns, normal lymphocytes; stippled columns, blast cells not labelled with "H-TdR: hatched columns, blast cells labelled with "H-TdR.

cells committed for division, because the labelling indices fell during the initial response to therapy. The higher incidence of aneuploid cells in the marrows of the patients in relapse may have been due to the effects of chemotherapy. It is improbable that the rate of de novo formation of aneuploid cells would have undergone any significant change during the few months between presentation and relapse, but it is probable, in the presence of the chemotherapy, that the aneuploid cells had a biological advantage so that their contribution to the population became noticeable. This change in the population of leukaemic cells during the course of the disease is in marked contrast to some of the model leukaemias in mice, the individual cells of which maintain fairly constant growth characteristics at all times12. This study suggests that generalizations about the growth characteristics of leukaemic blast cells without particular attention to the phase of the disease at which they are investigated should be made with caution.

We thank Dr N. Bishun for the chromosome analyses and Mrs Susan Hayward for technical assistance. This work was supported by grants from the Leukaemia Research Fund, the Medical Research Council, the British Empire Cancer Campaign for Research and the US Public Health Service.

Radiosensitization of Bacterial and Mammalian Cells by Substituted Glyoxals

by M. J. ASH WOOD-SMITH D.'M. ROBINSON* J. H. BARNES BRYN A. BRIDGES

Radiobiological Research Unit, Harwell, Didcot, Berkshire Methylglyoxal preferentially sensitizes anoxic bacterial and mammalian cells to the lethal effects of ionizing radiation. The radio-protective effect of anoxia on mammalian cells is effectively abolished in the presence of methylglyoxal, whereas sensitization of oxygenated mammalian cells is slight.

SEVERAL different classes of compound enhance the lethal effects of X-rays on various bacterial and mammalian cell systems. In view of the suspicion that anoxic foci are largely responsible for the radiation resistance of some tumours, the potential therapeutic usefulness of agents which could act preferentially in sensitizing anoxic cancer cells to X-ray induced cell killing is obvious. Some, but not all, sulphydryl reagents exert such an effect on bacteria¹, but they are in general too toxic for use with mammalian cells.

The effectiveness and the mechanisms of action of those chemical sensitizers which react with SH groups, such as N-ethylmaleimide, p-mercuribenzoate, iodoacetic acid and iodoacetamide have recently been reviewed by Bridges². Adams and Dewey³ have demonstrated, with bacterial

systems, the sensitizing properties of diacetyl, CH₃C.C.CH₃, and various other carbonyl compounds. These authors have produced experimental evidence to support a most interesting theory which accounts for the radiosensitizing properties of compounds in which carbonyl groups constitute part of a conjugated system of double bonds. According to theory compounds of this type can capture and stabilize, through resonance, hydrated electrons produced by the ionizing radiation. The radical anion produced is longer lived than the free hydrated electron and thus possesses an extended sphere of activity compared with the hydrated electron. Many such compounds which can form long lived radicals during irradiation, however, can also react with SH groups and it is still not clear what contribution is made by this latter property to their radiosensitizing activity.

Methylglyoxal, CH₃C.C, has been shown to inhibit

protein synthesis in bacterial cells and to prevent cell division⁴. This compound is widespread in nature and reacts reversibly with many naturally occurring thiols. In view of the interesting reactions of methylglyoxal with thiols, and especially with glutathione, we decided to investigate the possible radiosensitizing action of this substance and of certain other substituted glyoxals. The experiments which are reported in this article demonstrate unequivocally the radiosensitizing properties of methylglyoxal for bacteria and for mammalian cells in culture.

Methylglyoxal was obtained as a 45 per cent aqueous solution (Aldrich Chemical Co., Milwaukee). Before use, this was redistilled at the water-pump. An aqueous fraction was obtained first, followed by a yellow green oil distilling over the approximate range $50^{\circ}-70^{\circ}$ C and dissolving in the earlier fraction to give a colourless, homogeneous distillate. The methylglyoxal contents of such distillates when estimated gravimetrically as the bis (3-nitrobenzoylhydrazone)⁵ ranged from 26 per cent to 42 per cent (w/v); the distillates had an acidic reaction

* Present address: Microbiological Research Establishment, Porton Down, near Sallsbury, Wiltshire.

and they were stored in the dark at 4° C. In addition. methylglyoxal was prepared by oxidation of acetone with selenium dioxide. The crude product, boiling point 32°-60° C at 13 mm, was dissolved in dry ether and dried over anhydrous sodium sulphate overnight. The ether was removed and the residue distilled at 12 mm when a fraction, boiling point $45^{\circ}-50^{\circ}$ C, was collected, the receiver being cooled in a mixture of acetone and solid carbon dioxide. The product contained $42 \cdot 0$ per cent carbon and 6.37 per cent hydrogen; calculated for C₃H₄O₂, 3/4 H₂O: 42·1 per cent carbon and 6·48 per cent hydrogen. Riley, Morley and Friend⁶ give the boiling point as 54° C at 10 mm, and Moulds and Riley⁷ give 57°-60° C at 20 mm. They report products containing a small proportion of water. When the commercial or freshly prepared samples were analysed by gel filtration on a column of 'Sephadex G-10' they were shown to contain at least four components differing in molecular weight, which absorbed ultra violet light at 2800 Å (Fig. 1). It is probable that these components are various polymeric forms of methylglyoxal. Gas chromatographic analysis also revealed the presence of at least four components. Samples of methylglyoxal from both sources proved to have similar biological properties.

Glyoxal was obtained from Hopkin and Williams, London, as a 30 per cent aqueous solution. Propylglyoxal was supplied by Professor A. Szent-Györgyi of Woods Hole, Massachusetts. Phenylglyoxal was obtained from Koch-Light Laboratories, Colnwood, England, in the form of a polymeric glass. This was dissolved in chloroform and the chloroform was removed by distillation, leaving a syrup which was distilled *in vacuo*. The pure monomer was collected in the boiling point range 87.5°-89° C at 10 mm (lit. boiling point 95°-97° C at 25 mm), then dissolved in ten volumes of hot water and allowed to crystallize, when white needles of the monohydrate separated and were dried in air, melting point 81°-83° C.

When methylglyoxal, as a neutral solution (0.2 molar), was given intraperitoneally to female mice of the Harwell R stock, weighing between 20 and 25 g, the LD_{50} (30 days)

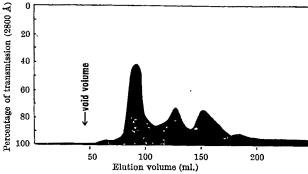

Fig. 1. Fractionation of methylglyoxal (2 molar) on a column (1.5 \times 90 cm) of 'Sephadex G–10'. The column was developed with distilled water at a flow rate of 26 ml/min and the absorption of the cluate at 2800 Å was measured and plotted against the clution volume.

was approximately 7 mmoles/kg (500 mg/kg). Doses of less than 6 mmoles/kg had no obvious toxic effects. LD_{50} values (30 days) for glyoxal and phenylglyoxal were 7 mmoles/kg and 1.8 mmoles/kg, respectively.

Sensitization by methylglyoxal was first demonstrated with the bacterium Serratia marcescens. Preliminary experiments established that the bacteria were not killed in the presence of methylglyoxal until concentrations greater than 5×10^{-2} molar were reached. Cells of Serratia marcescens grown in nutrient broth at 30° C were collected during the logarithmic growth phase, suspended in phosphate buffer (M/15, pH 6.8) and irradiated at 4° C with gamma rays from sources of cobalt-60 at a dose rate of approximately 4.8 krads/min. Nitrogen was bubbled continuously during and for 6 min before irradiation. Surviving bacterial cells were estimated by colony counts after plating on nutrient agar and incubating at 30° C for 24 h. Irradiations were made in the presence and absence of methylglyoxal, both in oxygen and in nitrogen. In most of the radiation experiments, methylglyoxal was

used at a concentration of 2×10^{-3} molar.

The cell line known as "clone A" originally derived from the ovary of the Chinese hamster by T. T. Puck (and subsequently cloned several times) was also sensitized by methylglyoxal. At the time of the experiments reported here, about 80 per cent of the population comprised cells containing the normal diploid number of twenty-two chromosomes. Cells were grown and manipulated according to the methods previously described. ments involved the application of methylglyoxal to cells, the growth medium was replaced by a pre-warmed, balanced salt solution to which was added the required amount of the drug from a cold, 0.4 per cent solution. Cells remained in contact with the drug for 20 min, whereupon the bathing fluid was removed and the cells irradiated. For irradiation in anoxic conditions, the cells, at four petri dishes for each dose, were sealed in a 'Perspex' container which was gassed with nitrogen for 10 min before irradiation (no oxygen could be detected in the effluent gas by a Beckman oxygen analyser). Cells were irradiated at room temperature in batches of four replicate plates for each dose. In all cases, the irradiations were performed with the bathing fluid removed in order to obtain full anoxia under nitrogen and to avoid unilateral absorption of energy, because the dishes were interposed between two Siemens therapeutic machines arranged to deliver 250 kVcp X-rays (8 m.amp, half value layer 1.2 mm of copper) at 620 rads/min. Immediately after irradiation the cells were washed with 199 medium, then given complete growth medium before incubation for 10 days in a gas (5 per cent carbon dioxide and 95 per cent oxygen) incubator. Control batches received all the appropriate treatments including sham irradiation in situ. inary toxicity experiments, all these manipulations were performed, with two exceptions: no tests were performed under anoxia and there were no irradiations. Surviving cells in all experiments are defined as those which produced colonies of fifty or more normal descendants after 10 days of incubation at 37° C; the only effect of irradiation studied is therefore cell killing. Two identical toxicity experiments were performed. In each case, four concentrations of methylglyoxal in a balanced salt solution were tested, and results of exposure of hamster cells to the drug for 20 min are shown in Table 1.

In the case of the irradiation experiments, the Harwell Atlas computer was programmed to analyse the results by an iterative least squares technique. The following relationship was assumed between surviving fraction (S) and dose (D)

where n is the extrapolation number and $D_{\rm 0}$ is the dose increment in rads to reduce any surviving fraction F on the exponential region of the survival curve to 0.37F. Survival values were determined at least twice for all treatments and, where no significant differences between

 $S = 1 - (1 - e^{-D}/D_0)^n$

experiments were detected by a computer test of consistency, the data were pooled for final analysis.

For Serratia marcescens, each experiment produced the same qualitative effect of methylglyoxal, but significant differences in extrapolation numbers between experiments made it impossible to pool the data. Accordingly, the results of a typical experiment are shown in Fig. 2 and the values of the parameters n and D_0 derived from these curves are listed in Table 2. In all the experiments the effect of methylglyoxal was found to be independent of dose for there was no significant difference in extrapolation number between curves 1 and 2 or between curves 3 and 4 (compare ref. 11). After this independence had been established, the ratios of the D_0 values with and without methylglyoxal were used as a measure of the relative effect of the drug. In all cases these were greater than unity, and a combined test of all values showed that the effect of methylglyoxal was significant (P < 0.1 per cent) both in oxygen and nitrogen (Table 2).

The magnitude of the radiosensitization produced by methylglyoxal was often greater than that shown in the present experiments. It is possible that variation from day to day results from changes in the relative concentration of the various polymeric forms of methylglyoxal always present in an aqueous solution. Both propyl- and phenylglyoxals sensitized anoxic bacterial cells to X-ray

induced cell death, but sufficient data are not yet available to make a detailed comparison of the effectiveness of these compounds. Glyoxal was inactive when tested in our system. It is important to note that the addition of irradiated bacteria to either non-irradiated or irradiated methylglyoxal did not result in enhanced bacterial lethality.

For Chinese hamster cells, complete uniformity was obtained throughout the experiments and no differences could be detected between them. Here therefore all the data were pooled and they are presented in Fig. 3, together with the derived values of n and D_0 in Table 3. Fig. 3 illustrates the curves of best fit obtained from the pooled data, extrapolated to zero dose. As with Serratia marcescens the effect of methylglyoxal was found to be completely dose-independent. Again the comparison of D_0 ratios showed that the effect of methylglyoxal was significant at the 0.1 per cent level in nitrogen and at the 10 per cent level in air. With the hamster cells, the radioprotective effect of anoxia (curve 4) was effectively abolished by exposure of anoxic cells to methylglyoxal (curve 3).

Table 3. RADIOSENSITIZING ACTION OF METHYLGLYONAL ON CHINESE HAMSTER CELLS IN TISSUE OULTURE

Curve 4:	control in nitrogen	1.67 ± 0.38	$\textbf{476} \pm \textbf{24}$	

It would be unwise to speculate at this stage on the possible mechanism of radiosensitization by methylglyoxal. It may be that methylglyoxal acts as a sensitizer in the way suggested for diacetyl by Adams and Dewey by forming a long lived stabilized radical. The reaction of methylglyoxal with thiol compounds, especially glutathione, and the possible involvement of the ubiquitous enzyme system, glyoxalase, in modifying radiosensitivity, however, cannot be excluded from consideration.

The observation that methylglyoxal at non-toxic concentrations overcomes the protective effect of anoxia when mammalian cells in tissue culture are irradiated with X-rays suggests that this compound might be effective in sensitizing to radiation tumours with anoxic foci without appreciably affecting the sensitivity of fully oxygenated cells. A preliminary study, in which methylglyoxal (4 mmoles/kg) was given to mice immediately before their exposure to an LD_{50} (780 rads) of X-rays, showed no evidence of enhancement of radiation lethality.

We thank Drs O. C. A. Scott and G. Adams of the British Empire Cancer Research Fund, Mount Vernon Hospital, Middlesex, for useful discussion and Mrs J. M. Copeland and Mrs D. M. R. Lowman for excellent technical assistance.

Carotid Rete and Brain Temperature of Cat

MARY ANN BAKER JAMES N. HAYWARD

Department of Anatomy and Brain Research Institute, University of California, Los Angeles, California

The plexus of arteries which make up the carotid rete in the cat seems to be able to modify the temperature of central arterial blood as it enters the cranial cavity.

Changes in the behavioural state of an animal are often accompanied by temperature fluctuations throughout the brain^{1,2}. Work on the rat³, monkey⁴ and rabbit⁵ has demonstrated a common factor underlying these intracranial temperature changes associated with feeding, sleeping and arousal—that is, a change in the temperature of the arterial blood perfusing the brain. The evidence that arterial blood temperature is the most important determinant of brain temperature in the monkey, rabbit and rat apparently contradicted the other findings in the

cat^{1,6-10}. When our experiments with the cat confirmed other reports that fluctuations (0·1-0·7° C) in brain temperature were independent of temperature fluctuations in the common carotid or aortic arterial blood, we began to suspect an important species difference in the regulation of brain temperature.

In the monkey and the rabbit the cerebral arterial blood at the circle of Willis is at the same temperature as the central arterial blood at the aortic arch4,5. This is to be expected because cerebral arterial blood in these

species enters the cranial cavity directly from the deeply coursing internal carotid and vertebral arteries. The cat has no internal carotid artery, however, and the circle of Willis is connected to the external carotid artery through the extracranial carotid rete. The physiological significance of this "rete mirabile"—a net-like arterial plexus present in some mammals—has remained an enigma since its description by Galen. Our studies suggest that the carotid rete in cats acts to modify the temperature of the central arterial blood as it enters the cranial cavity. We have concluded that the variations in brain temperature in the unanaesthetized cat are the result of neither local changes in neuronal heat production nor local changes in cerebral blood flow, as others have suggested, but rather, they originate in variations in the temperature of the cerebral arterial blood.

Since the comparative study by Tandler¹¹ in 1899 the arterial system of the head has been known to differ greatly between mammalian species. Daniel et al.12 have demonstrated that the rat, rabbit and dog have an intact internal carotid artery and a cerebral arterial supply similar to that of man and other primates13. On the other hand, the cat, together with the sheep, goat, ox and pig, derives most of the arterial supply to the anterior part of the circle of Willis from the carotid rete, a plexus of arteries formed principally by branches of the external carotid artery. In the cat the carotid rete lies outside the cranial cavity, near the apex of the orbit, and is termed an 'extracranial rete''12, while in the artiodactyls the rete is intracranial, lying in the cavernous sinus at the base of the skull. Neither Daniel et al.12 nor Davis and Story14, in their work on the carotid circulation of the cat, could demonstrate a patent internal carotid artery in their specimens, and both suggest that the contribution to the circle of Willis from the extracranial rete is the chief blood supply to the brain of the cat. Other studies involving the injection of dyes into live animals 15 showed that the carotid rete and its contribution to the circle of Willis supplies almost the entire brain of the cat. The rete might be haemodynamically important, as has been suggested12. Our preliminary studies indicate that the extracranial rete in the cat has a profound effect on brain temperature which may have significant thermoregulatory consequences.

We used four adult cats—male and female. Copperconstant an arc-welded thermocouples in glass tubing (outer diameter $0.7~\rm mm$) were implanted stereotaxically 16 in the brainstem at the level of the preoptic region. Two or three thermojunctions were cemented in the same glass tube for measurement of temperature at different vertical levels in the same frontal plane, and the probes were lowered through the brain into the subarachnoid space to lie on the vessels of the circle of Willis. We have shown in the monkey4 and the rabbit5 that the temperature of the cerebral arterial blood, measured in this way in the basal subarachnoid space, rapidly reflects changes in the temperature of the aortic and carotid blood. We measured central arterial blood temperature with thermocouples in polyethylene tubing (outer diameter 0.6 mm) threaded to the aortic arch through the common carotid artery (two animals) or into the common carotid through its inferior thyroid branch (two animals). Temperature at the extracranial rete was measured with thermocouples in polyethylene tubing passed retroconjunctivally from the supra-orbital process along the roof of the orbit to lie in or near the rete itself. Skin temperature was measured by a thermocouple implanted subcutaneously on the dorsal surface of the ear. Distal ends of the thermocouples were attached to miniature copper-constantan connectors cemented to a lucite platform elevated above the intact scalp on four epidural stainless steel screws, thus avoiding an artificial heat sink of dental cement over the cranium Aortic, orbital and ear thermocouples were threaded subcutaneously to the skull platform. An electroencephalogram was monitored between the two rear

screws supporting the platform. We used an Offner Type-R ink-writing oscillograph which provided continuous and simultaneous electroencephalogram and temperature records. Reference junctions in a bath of distilled water and crushed ice were used, and thermopotentials were amplified with a chopper-stabilized d.c. amplifier. The maximum sensitivity of the recording system was 0.025° C/mm pen deflexion. We recorded for more than 100 h from four unrestrained cats in a sound-attenuated, temperature controlled environmental chamber at 25° C, with one-way glass to permit observation of behaviour.

Accustomed as we had been to studying the monkey and the rabbit, in which intracranial temperature changes were related to similar changes in central arterial temperature^{4,5}, the independence of intracranial temperature from carotid temperature in the cat was very striking (Fig. 1). While the central arterial blood temperature in the cat remains rather steady, large, rapid changes in temperature related to sleep-waking cycles, occur throughout the cranium. There is no constant relationship between the temperature levels of the cranial sites and the level of the central blood temperature. As others have reported, in both anaesthetized and unanaesthetized cats1,6-10,17, at any time the central blood temperature might be higher, lower, or the same as the temperature of any site in the brain. In the rabbit and the monkey, a constant temperature gradient exists over hours, weeks and months between every brain site and both the central and the cerebral arterial blood, for there is no gradient between central and cerebral arterial blood in these species4,5. In the cat, on the other hand, while there is no constant temperature difference between brain and the central (aortic or carotid) arterial blood, there is a stable temperature gradient between brain sites and cerebral arterial blood measured at the circle of Willis (Figs. 1 and 2). It seemed thus that the behaviour-related temperature changes in the brain of the cat did originate in arterial blood temperature changes, but that the thermal state of the central arterial blood was modified on the way

The presence of the extracranial carotid rete is the most important cerebrovascular difference between the cat and the other species we have studied, and so we investigated the temperature of the rete and found that it was usually lower than cerebral arterial temperatures in the relaxed animal, but that the temperature gradient

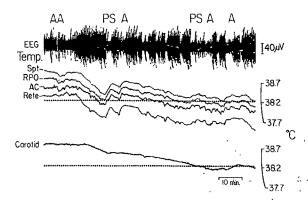

Fig. 1. Cranial and central temperature changes associated with slep and arousal in a free moving cat. Ambient temperature 25° C. The record began when the chamber door was closed after the animal was prepared for recording, and he is very excited and active (AA). Notice the drop in cranial temperatures as he falls into slow sleep (high voltage electroencephalograph, unlabelled). Rises in cranial temperatures are associated with periods of paradoxical sleep (PS) and spontaneous arousal (A). The central arterial blood temperature (carotid) shows a slow, steady decline in the 1-5 h recording, parallel to that of the cranial sites, but does not exhibit the same rapid temperature fluctuations. EEG, biparietal cortical electroencephalogram; Spt, midline septal region, 6.5 mm from the basal subarachnoid space; RPO, preoptic region, 1-6 mm from the basal subarachnoid space; AC, anterior cerebral artery, immediately rostral to optic chiaem and between the optic nerves; carotid, patent common carotid artery, at the level of the inferior thyroid artery; Rete, extracranial rete, near the apex of the orbit. The temperature, trace of the rete has been lowered 0.25° C for clarity.

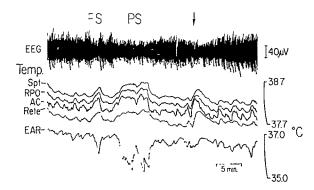

Fig. 2. Deep and peripheral cranial temperature changes in the cat in sleep and arousal. Ambient temperature 25° C. The record begins while the animal is in a period of slow sleep (unlabelled). Notice the rise in cranial temperatures and the fall in skin temperature (EAR) during episodes of paradoxical sleep (PS). At the arrow, the animal was awakened by banging on the recording chamber, and he jumped up and moved around before felling to sleep again. Labels the same as in Fig. 1 except EAR, subcutaneous temperature of the dorsal surface of the ear. The temperature trace of the rete has been lowered 0.25° C for clarity.

between intracranial structures and the extracranial rete was variable (Fig. 1). The temperature measured at the extracranial rete showed fluctuations similar to those observed at the anterior cerebral artery and in the brainstem (Figs. 1 and 2). Thus the temperature fluctuations in the brain of the cat which occur with arousal and with sleep cycles occur in parallel with similar fluctuations both at the circle of Willis at the base of the brain and outside the skull at the extracranial rete.

Upon arousal from slow sleep (high voltage electroencephalogram), during paradoxical sleep⁸ or when the animal is disturbed by noises, the temperatures of the cranial structures rise (Figs. 1 and 2), while the central arterial blood temperature remains steady (Fig. 1). Longterm changes in central blood temperature may parallel those of the cranial sites (Fig. 1), but the rapid changes in cerebral arterial blood and brain temperature which occur with arousal and with paradoxical sleep are not present in the central arterial blood. Subcutaneous temperature of the ear usually showed an inverse relationship to the cranial temperature changes (Fig. 2). We have described a peripheral vasconstriction and a rise in arterial blood and brain temperature during paradoxical sleep in the rabbit⁵.

In the cat^{6,9,10}, monkey and rabbit^{4,5} there is a gradient of increasing temperature from the arteries in the basal subarachnoid space toward the centre of the brain. The cerebral arterial blood is cooler than the heat-producing nervous tissue in all species, and so this gradient is expected4,5,17,18. Brain temperatures decrease towards the surface of the hemispheres, presumably because of the hemispheric subarachnoid arterial net and the influence of environmental cooling on the superficial brain sites4,6,19.

Our studies suggest that the changes in brain temperature of the cat in sleep and arousal originate in temperature changes in the cerebral arterial blood. Our finding that parallel changes in temperature occur outside the cranium at the extracranial rete, and inside the cranial cavity at the basal arteries and in the brain, with no relationship to arterial blood temperature high in the common carotid artery, suggests that the temperature of the central arterial blood in the cat is modified across the extracranial rete.

Both the configuration and the location of the rete suggest that it is vulnerable to various thermal influences. The extracranial rete lies within a venous lake12,14, and the large surface area of the interlacing network of vessels may permit a "countercurrent" exchange of heat between the arterial blood of the rete and the venous return from various regions of the head. Our observations of inverse temperature changes occurring between ear skin and rete (Fig. 2) suggest that cranial peripheral vasomotor changes and changes in heat loss from the head influence the temperature of arterial blood in the extracranial rete by such a countercurrent mechanism. Furthermore, the close relationship of the rete to the cranial, oral and nasal cavities and to the muscles of mastication suggests that the temperature of the blood in the plexus of arteries might be altered by cerebral venous blood, the temperature of the food or of the respiratory gases19, muscular heat production, or vascular changes in the mucosa of the oral or nasal passages.

The full significance of these findings for thermoregulation in the cat remains to be studied. Since the localization of thermosensitive regions in the hypothalamus²⁰, it has been assumed that information about the thermal state of the body core may be carried rapidly to central thermoreceptors by the arterial blood²¹. In the cat, however, because of temperature changes across the carotid rete, large thermal changes occur in the cerebral arterial blood and in the hypothalamus without concomitant changes in deep body temperature. The hypothalamus of the cat is thus exposed to temperature shifts which do not appear to be of primary thermoregulatory significance. Any theory of temperature regulation in the cat must take into account this dissociation between the thermal changes occurring in the hypothalamus and those of the body core.

Reports of thermosensitive regions in the medulla of the cat^{22,23} suggest that lower brainstem regions within the area of supply of the vertebral-basilar system¹⁵ may be involved in thermoregulation in this species. expect that the behaviour related temperature fluctuations in the rostral brainstem would not be present in the lower medulla, for the vertebral arterial blood comes directly from thoracic arteries and does not traverse a rete. In the cat, the presence of dual thermosensitive zones bathed by blood from thermally divergent sources suggests a "two-tiered"21 control of homeothermy. There may be a basically different mode of thermoregulation in the internal carotid animals in which the cerebral arterial blood is thermally homogeneous4,5. We conclude that the species differences in the cerebral circulation may be important in the central neural organization for the regulation of body temperature.

This work was supported in part by a grant from the US Public Health Service. We thank Mrs Enola Burrell for technical assistance and Miss Keiko Tani for preparation of the figures.

LETTERS TO THE EDITOR

PLANETARY SCIENCE

Observation of Raman Scattering from the Atmosphere using a Pulsed Nitrogen Ultraviolet Laser

This communication reports the experimental observation of optical Raman scattering from oxygen and nitrogen in the atmosphere using a pulsed nitrogen ultraviolet laser^{1,2} as a light source. Previous atmospheric laser scattering experiments have been reported^{3,4} which utilized Rayleigh scattering or scattering from particulate matter such as aerosols and dust particles. With Raman scattering, the wavelength of the scattered light is shifted, the amount of the shift being specific to the scattering molecule. The importance of the Raman scattering technique is that it enables a range resolved measurement of atmospheric constituents, with respect to both species and concentration, from a single remote location. This type of measurement could be useful in such fields as meteorology, atmospheric physics and air pollution control.

The apparatus used in the Raman scattering experiments is shown in Fig. 1. The transmitter consisted of an uncollimated 100 kW peak power, 10 nsec, 3371 Å pulsed nitrogen laser (Avco model C-102). A 20 cm diameter, 1.6 m focal length telescope and an RCA 7265 photomultiplier with an S-20 cathode response served as the receiver. Continuous wavelength selection was obtained by tilting interference filters away from normal incidence. Two interference filters were used, each with a transmission band width of 35 Å at half maximum. The transmissions for these filters were centred at 3557 Å and 3658 Å for normal incidence. A maximum filter tilt angle of 35° was possible with the apparatus, yielding a maximum wavelength shift of approximately 200 Å. The experiment was conducted at Everett, Massachusetts, at times shortly after sunset during July 1967.

A spectral analysis of the experimentally obtained air scattering return at zero elevation is shown in Fig. 2. In addition to the strong return at the 3371 Å transmitter wavelength, signals, weaker by about a factor of 1,000,

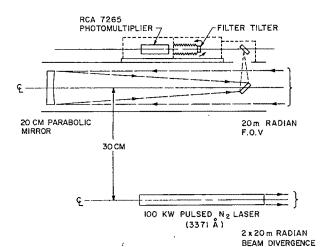

Fig. 1. Schematic diagram of the apparatus used to observe atmospheric Raman scattering.

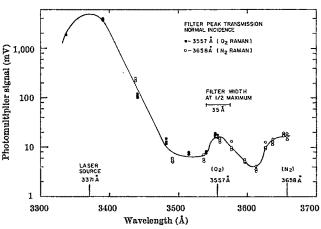

Fig. 2. Photomultiplier signal from atmospheric backscatter as a function of wavelength. Each data point represents a single measurement obtained with one laser pulse.

were observed at 3557 Å and 3658 Å, corresponding to the vibrational Raman shift for oxygen and nitrogen, respectively. The magnitude of the observed Raman signals was consistent with the expected signal calculated on the basis of an estimated Raman cross-section of 10^{-29} cm². Measurements of this type can be used to obtain directly the oxygen to nitrogen concentration ratio as a function of range.

The apparent spectral width of the experimental back-scatter signal in Fig. 2 near the laser line at 3371 Å is thought to result from the rejection properties of the interference filter. This was determined by comparing the air backscatter near 3371 Å with the return from a solid target. No significant difference, as a function of wavelength, was observed when the target signals were normalized to the air backscatter.

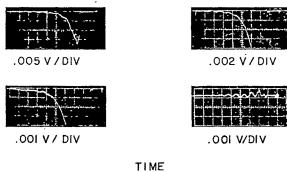

It is hoped that, with improvements in both resolution and rejection, Raman signals can be observed in this wavelength region from other sources. Signals originating from rotational transitions in oxygen and nitrogen, infrared transitions in various atmospheric contaminants, and vibrational transitions in small solid air-borne particles are of particular interest.

Typical oscillograms of the photomultiplier signal, obtained at the 3658 Å nitrogen Raman line, are shown in Fig. 3. At the beginning the observed pulse shape is dominated by the non-coaxial transmitter-receiver geometry. When the fields of view of the transmitter and receiver have sufficiently overlapped, the signal decay can be fitted to an inverse squared law multiplied by an exponential extinction. The signals shown in Fig. 3 yield useful data for up to 8 µsec, which corresponds to a range of 1·2 km. The application of photon counting methods, with pulses averaging 100/sec for several seconds, should greatly extend the useful range with the same laser transmitter power.

A range resolved measurement of backscattered power in the Raman echo pulse in Fig. 3 can be shown⁵ to yield directly the atmospheric transmission at the range of interest. Range-gated atmospheric Raman scattering may thus be useful in single ended transmissometer applications. Previously proposed single ended transmissometers⁶ suffered from a lack of complete knowledge of the relationship between the backscatter from the suspended particles, causing the reduced visibility, and the transmission through them, and relied therefore on an analysis of the backscatter pulse shape, rather than a simple power measurement.

The 3371 Å pulsed nitrogen laser was chosen from among the available strong laser sources for the following reasons. Raman scattering cross-sections vary inversely with the fourth power of the incident wavelength. Thus the pulsed nitrogen laser is more effective than a ruby laser by a

No RAMAN SCATTERING (λ= 3658 Å)

factor of $(6940/3371)^4 = 17.96$. The photoefficiency of photocathodes is much higher in the ultraviolet than in the near infrared. With a 6940 Å ruby source the nitrogen Raman line is shifted to 8280 Å where the best photoefficiency (S-1) is about 0.4 per cent compared with 10 per cent for the S-20 surface at 3658 Å. Thus a factor of 25 in favour of the pulsed nitrogen laser results.

The product of the foregoing two factors is $17.96 \times 25 =$ 449. When the difference in energy for each photon is taken into account, it is found that the 100 kW pulsed nitrogen laser is as effective in producing Raman scattered photoelectrons as would be a ruby laser of 21.8 MW with the same pulse width. The nitrogen laser has the further advantage of a high repetition rate capability (100 pulses per second) which permits rapid scanning or signal averaging.

I thank Mr Henry Smith for his very fine technical assistance.

Graphical Representation of Mantle Convection

COMMUNICATIONS which deal with mantle convection usually fall into one of two groups. The geological approach is to assume the East Pacific rise and Atlantic ridge systems to be loci of rising mantle material, which, after flowing parallel to the Earth's surface, sinks again in the vicinity of the East Indian and Caribbean trenches or the young mountain systems of western America and Eurasia. Good examples are given by Girdler¹ and Wilson². No attempt is made to portray the forms of convection cells within the mantle.

The theoretical approach was well illustrated in Licht³ and Runcorn4. Symmetrical sets of flow cells, usually of three- to five-fold symmetry, are displayed on a global There is no particular correlation between the cell locations and surface geology.

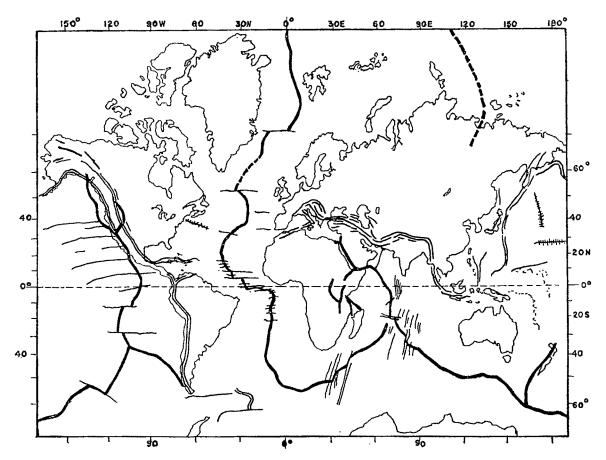

Fig. 1. Mercator's projection showing rifts (----), trenches and tertiary mountain systems (=----)

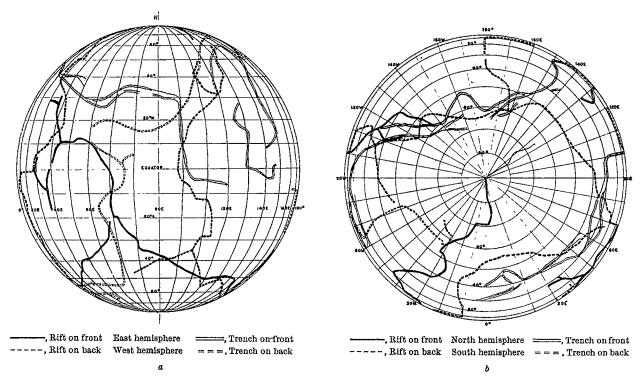

Fig. 2. a, Equatorial projection of surface features indicating convection. b, Polar projection of surface features indicating convection.

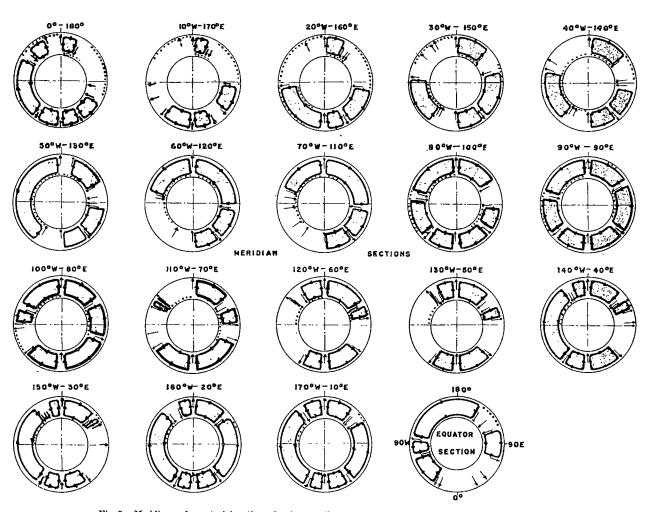

Fig. 3. Meridian and equatorial sections showing mantle convection cells. ..., Flow direction out of paper.

It seems attractive to attempt a matching of the theoretical mantle cells with the significant surface geological features. The procedure, of course, is quite simple: after outlining the rises and trenches on a global projection, one slices the appropriate sections to expose the mantle. The convection cells should then be contained between successive "up" and "down" points on the circumference.

Fig. 1 is a Mercator's projection showing the location of known rift, tertiary mountain and trench systems^{2,5}. These are transformed to equatorial and polar projections in Fig. 2a and b. The sections shown in Fig. 3 are obtained either by cutting through the equator in Fig. 2a, or by slicing meridians at successive 10° angles from Fig. 2b. For clarification, the cells are drawn to fill the entire mantle. The small dots indicate flow components normal to the section.

In the equatorial section of Fig. 3, only four asymmetrical cells appear. The larger empty area encompasses Africa, which is partially enclosed by a rift system; the smaller corresponds to the East Indian trench.

A descending column has been introduced at the South Pole in all the meridian sections. The justification for this is the presence of the Antarctic mountain system, connected to the Patagonian Andes by the Scotian arc. The meridian slices consequently show some symmetry at the poles, although the cells are far from uniform in size.

Theoretical studies, involving spherical harmonic analysis of the topography of the Earth's surface and of the geopotential^{4,7,8}, indicate that the pattern of mantle convection has changed, with the growth of the Earth's dense core, from a first order harmonic mode to the fourth or fifth at present. Thus there would now be eight or ten convection cells in the mantle. None of the sections shown in Fig. 3, however, has more than six cells, while

eight of them have only four cells. The small number of cells and the many gaps between them do not fit any symmetrical theoretical model. It is unrealistic to assume that the somewhat random distribution of rift and trench systems—and of land masses—is controlled by a perfectly regular system of convection cells in the mantle.

There is some three dimensional character to the convection systems displayed in Fig. 3. They resemble sectorial and tesseral harmonics, lying north south in the western hemisphere, less complete and principally east—west in the eastern.

Heat flow measurements ought to provide significant evidence of mantle convection, for rising currents are marked by high heat flow and vice versa. Fig. 4 shows heat flow zones which are known, based on the work of Lee and Uyeda 10, plus later data. The world mean heat flow is given as 1.5 ± 10 per cent $\mu \text{cal/cm}^2/\text{sec}$. Because 80 per cent of the measurements have been made in ocean bottoms, many of these in rift—rise areas, this figure may be high.

Average heat flow of the rift—rise systems (50 areas of 186) is 2·4 µcal/cm²/sec, while the average in trench and young mountain regions is 1·36 (32 of 180). Thus the former areas are anomalously high, but the latter are only slightly below average. The zones of lowest heat flow (average 1·0 or less) appear to be adjacent to the rifts, chiefly in ocean basins. A definite pattern of heat flow anomalies will require many more measurements, particularly in land areas.

If convection is taking place in the mantle, the rising streams appear to be located beneath the rifts and ridges, based on high heat flow and, to a lesser degree, on low gravity in these areas. Equivalent indications of the descending streams, however, are not very clear. The cell system is generally incomplete, irregular and of

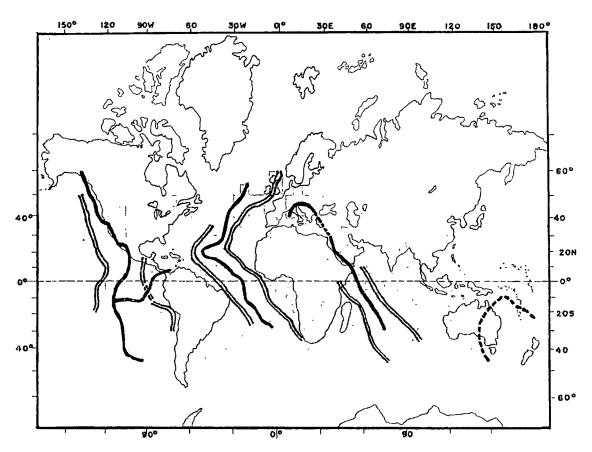

Fig. 4. Mercator's projection showing zones of anomalous heat flow. —, High heat flow; —, low heat flow.

limited angular extent. Consequently, convection would be confined to the upper few hundred kilometres of the mantle^{11,12}.

Photogeological Investigation of the Mozambique Front in Tanzania

THE boundary between the Tanganyika Shield and the Mozambique Orogenic Belt in north-central Tanzania is being investigated by means of an initial photogeological study of an area of about 70,000 square miles, making use of the extensive reconnaissance mapping by the Tanzania Geological Survey.

Seventeen "tectonic domains" were established photogeologically and their distribution agrees with the known extent of the Tanganyika Shield and the Mozambique Orogenic Belt. The interpretation showed that it was possible to recognize photogeologically the following major features, most of which were already well known²⁻⁶: the general north-south trend of the Mozambique Belt and, in contrast, the east-south-east trend of many of the folds within it which strike across the Belt: the identity of the Tanganyika Shield, a vast extent of granite, with steeply dipping Nyanzian metasediments and a flat-lying cover of Bukoban (Proterozoic) rocks in the north; the boundary between the Shield and the Mozambique Orogenic Belt defined by steeply dipping marginal quartzites with northerly strike in the Serengeti; the ancient Dodoman and Nyanzian orogenic belts which strike east-south-east within the Shield; and the occurrence of probable basement rocks older than the Usagaran metasediments within the Mozambique Belt.

To amplify these observations and to make possible further photogeological and tectonic interpretations, we carried out field work at the end of 1966. Observations were made over 6,000 miles of traverse, and five areas lying across the boundary were examined in some detail (Fig. 1).

A transition zone, which lies between the (cratonic) Tanganyika Shield and the (orogenic) Mozambique Belt, takes a variety of forms which must reflect different tectonic environments along the margin. Thus in the north, flat-lying nappes of Usagaran metasediments approach the cataclastically deformed margin of the Further south, around Kondoa, a transition through zones of cataclasis, thrusting and of plastic deformation, shows beyond doubt that many of the gneisses previously thought to belong to the Usagaran System are tectonically derived from the pre-Usagaran basement.

The charnockites which occur at the margin of the Shield at Msagali7 were intruded by, and partially converted to, granite. This may correspond to the pre-Mozambiquian event which has tentatively been equated2 with the epoch of granitization in which the Shield developed as a megastructural unit. Our field work showed that the resulting complex was tectonized and converted into well foliated and rodded gneisses in the Mozambique orogeny. Farther south the Orogenic Belt consists entirely of Usagaran metasediments flanked by the much-discussed Konse System which may be analogous to the Umkondo System of Rhodesia,10.

Cahen¹¹ and Harpum³ have suggested that the Mozambique Belt may contain, and partly consists of, relics of rocks metamorphosed in earlier cycles, and this is confirmed by the recognition both photogeologically and on the ground of tectonized relics of basement rocks for up to 50 miles within the Belt. We do not consider that any of the charnockitic rocks we saw in the Mozambique Belt owe their high grade to metamorphism during the Mozambiquian orogeny.

The Mozambique Belt in Tanzania is largely a tectonic unit which owes its common characteristics to the effects of one dominant orogenic deformation. In view of the different opinions which have been expressed about the status of small scale structures near orogenic fronts, it is

interesting to observe that the main effect of the deformation is a preponderance of strongly developed linear structures such as tight, rodded, reclined folds, mullions and stretched conglomerates which plunge to the east-southeast and south-east. This axial direction, which is transverse to the general northerly trend of the orogenic belt, is

the main direction of transport and stretching. It is the

Usagaran metasediments Psammiles, petites and semi-petites Area in which some detailed mapping was done Quartzo-feldspathic gneiss Margin of volcanics Usagaran Reworked basement Granitoid Shield Konse Series Granite **a** 100 150 kms Same Market ťη $\boldsymbol{\omega}$ $\boldsymbol{\pi}$

Fig. 1. The Mozambique Front in central Tanzania, showing the relationship between the Usagaran metasediments, the Tanganyika Shield and the pre-Usagaran basement, which consists of tectonized gneisses of various origins.

common axis of the majority of small scale structures not only within this part of the Mozambique Belt but also within the cataclastically and plastically deformed margin of the granitoid Shield. This precludes the possibility that the east-south-east plunging structures belong to a pre-Mozambiquian east-south-east trending orogeny. These structures are mainly expressed on a mesoscopic scale, but some can be recognized photogeologically.

Folding on north-north-east axes overturned to the west occurs in comparatively small areas near to the orogenic front. This may be later than the structures

trending east-south-east.

There are noteworthy resemblances between the relationships which we have observed in Tanzania and those described by Sanders¹² in western Kenya at the junction of the Mozambique Belt and its foreland.

Photogeological interpretation of the selected areas and extrapolation of the results with the intention of constructing a tectonic map of the boundary region is continuing. We hope to be able to show the variations along, and to draw tectonic sections across, a larger section of an orogenic front than has previously been possible.

ASTRONOMY

Possible Circular Polarization of Compact Quasars

WE wish to point out in this communication that both the radio and optical radiation from compact quasars may be circularly polarized. We consider here the situations in which this polarization is most likely to be detectable, and discuss the theoretical implications if it should be found.

The synchrotron radiation from a system of relativistic electrons moving in a uniform magnetic field of strength H gauss, with an isotropic distribution of pitch

angles, will be circularly polarized by $\sim 100 \left(\frac{v_L}{v_L}\right)^{\frac{1}{2}}$ per

cent^{1,2}, ν_L being the electron gyrofrequency (~3 H Mc/s): the precise value depends on the electron energy spectrum and on the observer's orientation relative to the field. Non-uniformities and self-absorption in the source would naturally diminish the observed degree of circular polarization.

In a typical radio galaxy with $H \sim 10^{-5}$ gauss, we would expect an unobservably small amount of circular polarization—≤ 0.1 per cent at ~100 Mc/s, and even less at higher frequencies. The percentage of polarization may, however, be much larger for compact quasars, the magnetic field of which (at least within the variable component) may be as great as between 1 and 100 gauss^{3,4} ($\nu_L \sim 3-300$ Mc/s). The radiation from these objects at, say, $\sim 3,000$ Mc/s could thus, in principle, he 3-30 per cent circularly polarized. The observed net polarization would, however, be reduced for three reasons. (a) The magnetic field in the compact component might be (b) Synchrotron self-absorption would non-uniform. destroy circular polarization within the compact component if the optical depth were large. (c) A contribution to the flux might come from a non-varying "halo" with a weaker magnetic field.

As regards (a), we note that the variable radio flux from 3C 273 is linearly polarized, so that the magnetic field in that case is probably fairly uniform. Moreover, the absence of linear polarization in other compact sources may be due to differential Faraday rotation, which would not affect circular polarization. To minimize the effects of self-absorption we suggest exploiting the proposal of several authors that the variable flux comes from a component which is expanding. If this idea is correct, the maximum flux is attained just when the expanding component starts to become transparent at the frequency of observation. Thus the consequences of (b) and (c) would simultaneously be minimized if observations were made at, or soon after, the time when the flux reaches a peak.

We conclude that the existence of at least about 1 per cent circular polarization in the radio emission from compact quasars is by no means unlikely. The chances of detecting it would be greatest if observations were made at a frequency where large amplitude intensity variations are known to occur (which restricts us to frequencies \gtrsim 1,000 Mc/s), at a time when the flux is just starting to decrease. If circular polarization were indeed observed it would provide evidence for the operation of the synchrotron process, and enable us to estimate the magnetic field strength directly. We would not, however, expect the observed degree of circular polarization to be exactly proportional to v-1 for the compact component would not contribute the same fraction of the total flux at different frequencies. Plasma radiation might also be circularly polarized in the presence of a magnetic field, but only in a narrow range of frequencies10.

We note finally that the optical continuum would not be circularly polarized if it is the result of synchrotron emission (unless the velocity distribution of the electrons had a very unlikely and anisotropic form). There is the alternative possibility, however, that the optical continuum results from inverse Compton scattering of radio synchrotron radiation^{3,4,11}, which may, as we have seen, possess significant circular polarization. Because inverse Compton scattering preserves polarization12,13, the optical continuum could then be circularly polarized by about 1 per cent. If the light from quasars were found to exhibit detectable circular polarization, this would therefore indicate that it arose from the inverse Compton process, and not from synchrotron emission.

Possible Instability in the Self-closure Phenomenon in Gravitational Collapse

PRESENT ideas on the nature of relativistic collapse are largely derived from the study of spherisymmetric models, the only ones readily accessible to mathematical analysis. The most striking feature of spherical collapse—the formation of a critical surface ("event horizon"), characterized by infinite gravitational red-shift, which divorces the collapsing object from the external observer—is believed also to typify realistic situations, at least if the asymmetries are not too large. The purpose of this communication is to point out that, on the contrary, models with exact spherical symmetry possess idiosyncrasies which render them dangerous, and perhaps misleading, as a basis for induction.

Ten years ago, Regge and Wheeler analysed small perturbations of Schwarzschild's spherically symmetric field of a point mass m. A curious result emerged from their formulae. Static perturbations exist which remain finite down to the event horizon r=2m, but these are all induced by the presence of exterior masses^{2,3}. All asymmetric static perturbations caused by sources within r=2m (such as a quadrupole moment) become singular on r=2m. This result has recently been codified as a rigorous theorem4: among all static, asymptotically flat vacuum fields with closed simply connected equipotential surfaces $g_{00} = \text{constant}$, Schwarzschild's solution is the only one which has a non-singular event horizon $g_{00} = 0$. It would seem that other fields with event horizons similarly have an exclusive status. For example, we have proved that the Reissner-Nordström solution for a charged particle is the only static, asymptotically flat electrovac field with a regular event horizon, and there is reason to suspect that Kerrs' rotating particle solution is similarly distinguished in the class of stationary fields.

Let us now consider the collapse of an asymmetric (non-rotating) star, on the assumption that an event horizon is formed. Because of the slowing-down of processes for the external observer, it seems reasonable to suppose—and this can be supported by arguments based on small-perturbations analysis—that it is permissible to treat the limiting external field as static. The foregoing theorem on singular event horizons then applies. Before reaching a singularity at the event horizon, the star will respond to the precursory large tidal forces in such a way as to subdue, if possible, the rise of the singularity itself. There are two possibilities.

The first is that the star shakes off its quadrupole and higher moments and is, so to speak, patted into spherical shape before crossing the event horizon. Some such idea has been suggested previously³. The chief difficulty here is to find a plausible mechanism which acts locally (to avoid the delay resulting from retarded-potential effects) and which will accomplish this task in the finite proper time available.

The second possibility, which has not been considered before, is that the event horizon becomes smudged out and obliterated. One is inclined at first to dismiss this alternative because one does not normally expect the qualitative character of a phenomenon to be destroyed by an arbitrarily small perturbation. To entertain it seriously, one would first have to be convinced that there exists a fully general class of collapse regimes which initially deviate arbitrarily little from spherical symmetry and which do not exhibit self-closure. Now there is actually a theorem which, although more limited in scope, does lend considerable support to this idea. We confine ourselves to the class of static, axi-symmetric vacuum ("Weyl") fields. It can be proved that there exists a general class of Weyl fields which deviate arbitrarily little from Schwarzschild's solution for $r \ge (1 + \sqrt{(2)})m$, which are analytical except for a particle like singularity (well within the gravitational radius r=2m) and which are free of event horizons.

The proof is simple. We write the metric of a Weyl field in the standard form⁵

$$ds^{2} = e^{2(\nu-\lambda)} (d \rho^{2} + dz^{2}) + \rho^{2} e^{-2\lambda} d\phi^{2} - e^{2\lambda} dt^{2}$$
 (1)

Einstein's vacuum field equations then require that $\lambda(\rho,z)$ satisfy

$$\partial^2 \lambda/\partial \rho^2 + \rho^{-1} \partial \lambda/\partial \rho + \partial^2 \lambda/\partial z^2 = 0$$

which is formally Laplace's equation in cylindrical coordinates. (The function $\nu(\rho,z)$ is derivable from λ by a quadrature.)

We first choose for λ the formal expression for the Newtonian potential of a uniform thin rod of mass m placed along the axial segment $\rho = 0$, $-m \le z \le m$. In this case, equation (1) is known to be a disguised form of Schwarzschild's line-element², the Schwarzschild radial co-ordinate r being given implicitly by

$$\rho^2/r(r-2m)+z^2/(r-m)^2=1$$

Expanding λ in spherical harmonics, we have

$$\lambda = -\sum_{n=0}^{\infty} (m/R)^{2n+1} P_{2n}(\cos \theta)/(2n+1)$$
 (2)

with R and θ defined by $\rho = R \sin \theta$ and $z = R \cos \theta$. The infinite series in equation (2) diverges logarithmically on the "sphere" R = m (not really a sphere, for r is variable over it, ranging from 2m at the poles to $(1 + \sqrt{(2)})m$ at the equator). For R < m, equation (2) has therefore to be replaced by

$$\lambda = -\sum_{n=0}^{\infty} (R/m)^{2n} P_{2n} (\cos \theta)/(2n+1)$$
 (3)

It is the analytic continuation of equation (1) cum equation (3) within the "rod" (in reality the sphere r=2m) which gives rise to the peculiarities of the extended Schwarzschild manifold—in particular, the appearance of an event horizon $g_{00}=-\mathrm{e}^{z\lambda}=0$ for r=2m.

We consider next the potential function λ_N obtained by truncating the series in equation (2) at the Nth term (or, more freely, by changing the coefficients, from the Nth term onwards, in any manner such that the modified power series in (m/R) has an infinite radius of convergence). By taking N sufficiently large, we can make the Weyl field associated with λ_N differ as little as we please. from spherical symmetry for R > m. The extension within R=m, however, differs utterly from equation (3). modified series in equation (2) representing λ_N continues to be valid for R < m, and it describes a manifold which is regular down to a multipole singularity at R=0. The theorem is thus established, for there is no infinite redshift surface in this solution. Inward-falling probes and light-rays penetrate well inside the gravitational radius in a co-ordinate time t comparable with Newtonian predictions. In the immediate vicinity of R=0 their behaviour is more complicated. It is easy to verify that equatorial probes aimed at the singularity reach it in finite proper and co-ordinate time. On the other hand, the corresponding co-ordinate time for a probe falling down the axis is infinite; but it is very possible that the axis is unique in this respect, and that this anomaly will vanish entirely when the assumption of exact axial symmetry is relaxed.

If, now, we are prepared to admit that the exterior field of a collapsing, nearly spherical star might be broadly similar in structure to such a static field, then we are led to an unexotic picture of collapse and re-expansion, to which Newtonian theory should provide a tolerable first approximation. The multipole singularity of the static vacuum field should be precluded in the dynamical case by the asymmetry of the motion. (Penrose-type theorems? on the inevitability of singularities are inapplicable here, because "trapped surfaces" are absent, that is, light signals can be sent outwards to infinity from any point of space.) From the astrophysical point of view, such a picture would, of course, provide a natural explanation of several otherwise puzzling features (extended

life-times, quasi-periodic variability, compactness) of the quasi-stellar sources, and might also explain the continued activity of the supernova remnants in the Crab

The principal question left open is the extent to which results established for static fields can provide information at all relevant to an essentially dynamical phenomenon. For nearly spherical situations, it can be argued that, as far as the exterior vacuum field is concerned, the output of gravitational radiation is necessarily small, and therefore the non-static aspects cannot be important. It is well, however, to be cautious: recent results in the theory of gravitational waves8 have hinted at unsuspected subtleties in the transition between stationary and nonstationary states. A full dynamical analysis of asymmetric collapse remains a problem for the future. Only such an analysis can determine how far the considerations presented here are true.

THE SOLID STATE

Permanent Magnet Properties of Platinum-Cobalt Alloys

Alloys of platinum-cobalt near the equiatomic composition can, by suitable heat treatment, undergo a disorder to order phase transformation which produces extreme magnetic hardness. Coercivities up to 6,800 oersteds have been observed at room temperature. Walmer¹ has recently given a comparative table of magnetic properties since the discovery of the alloys in 1936 by Jellinghaus2, in which the coercivities obtainable have risen from 4,000 to 4,300 oersteds (1961) and the energy product $(BH)_{\text{max}}$ from 4.6×10^6 to 9.5×10^6 gauss-oersteds. Walmer also includes a polar diagram which shows how the coercivity varies with crystallographic direction. A maximum of 6,800 is observed in <111> and 4,300 oersteds in <100>. Table 2 of Walmer's article lists the optimum magnetic properties as follows:

These properties have been further improved by Chaston³, who obtained an energy product of 10.3×10^6 gauss-oersteds, a remanence of 7,125 gauss and a coercivity of 4,430 oersteds.

The purpose of the present communication is to report work which has produced many more detailed results and considerably improved permanent magnet properties.

An alloy of platinum-cobalt containing 52.12 atomic per cent cobalt was prepared by melting the pure constituents in an argon arc furnace. The ingot was then homogenized in a vacuum furnace at 1,200° C for 12 h. The measured density of the resulting alloy was 15.55 g/cm³ which was in good agreement with that calculated by X-ray analysis.

A thin disk of the alloy (about 0.5 cm diameter \times 0.03 cm thick) was disordered by holding at 1,000° C for 0.5 h. It was then quenched and aged for 20 min at 695° C. The resulting magnetic properties are shown in the table below.

> $\begin{array}{lll} \mbox{Coercivity} & H_c & = 4,900 \mbox{ oersteds} \\ \mbox{Remanence coercivity} & H_R & = 5,200 \mbox{ oersteds} \\ \mbox{Remanence} & B_r & 5,280 \mbox{ gauss} \\ \mbox{Maximum energy product} & (BH)_{\rm max} & = 14.1 \times 10^{9} \mbox{ gauss-oersteds} \\ \end{array}$ All the measurements were made at 24° C.

(The remanence coercivity is the reverse field required to reduce the remanence to zero, whereas the intrinsic coercivity is the reverse field required to reduce the magnetization to zero while the field is still on.)

As far as I know this value of $(BH)_{\max}$ is the highest ever recorded for any permanent magnet material.

It should be emphasized that these properties were obtained by using a maximum magnetizing field of 15,000 oersteds. Because the uniaxial magnetocrystalline anisotropy of the ordered tetragonal phase is at least1 of the order of 2×10^7 erg/cm³ it is clear that this field would not be sufficient to produce saturation. (More recent measurements by Brissoneau et al.4 have shown that $K_1 \sim 5 \times 10^7 \text{ erg/em}^3$.)

Investigation of the properties of single crystals of the alloy which has been carried out in some detail⁵ has shown that there is considerable anisotropy of properties even when the specimen consists of a mixture of the cubic and tetragonal phases. Initially, of course, the specimen is a face centred cubic single crystal. Subsequent heat treatment produces platelets^{1,5,6} of the high anisotropy ordered tetragonal phase on (110) planes. The optimum permanent magnet properties obtained with the crystal ((112) orientation) are given in Table 1.

Table 1 Coercivity, H_σ 1111 1 110 1100 Coercivity, H_σ 3,500 oersteds 3,000 oersteds Remanence coercivity, H_R 3,800 oersteds 3,300 oersteds Remanence, B_r 6,065 gauss 4,050 gauss Energy product $(BH)_{\max}$ 11.0 × 10° gauss-oersteds 6.9 × 10° gauss-oersteds

More details of these properties, and in particular the temperature variation, from both an experimental and a theoretical standpoint have recently been discussed by McCurrie and Gaunt⁵ and Gaunt⁶.

From this work it seems very probable that the potential permanent magnetic properties of platinum cobalt alloys have not yet been fully realized. Further work will almost certainly lead to increases in the coercivity, but the most difficult problem is that of increasing the remanent magnetization-the absolute maximum is, of course, defined by the saturation magnetization of the cubic phase, that is, about 8,800 gauss depending on the cobalt content.

Pre-yield Relaxation and the Yielding of Single Crystals of Iron

In tensile tests on polycrystalline iron at the usual rates of strain, if the process of strain is repeatedly interrupted for intervals of three minutes at stresses below the usual upper yield stress, the load immediately falls because of relaxation. If, after this, the process of strain is halted at roughly the upper yield stress of an uninterrupted test, there is no immediate relaxation; instead the load is maintained for a delay period of 2·3-90 sec, when there is sudden yielding and relaxation to the lower yield stress¹. I accounted for such a period without load drop by a reduction of the number of mobile dislocations (or of operative dislocation sources) by the series of relaxations. This explanation was strengthened by the observation that if after relaxation from a pre-yield stress, the stress is brought back to its original value by further straining, a further relaxation gives a smaller load drop. It was expected that single crystals would behave differently from polycrystalline material, and this has now been verified.

Results for two single crystals of iron, a crystal with 3.25 per cent silicon and a specimen of polycrystalline iron from the same heat as the iron crystals, are given in Fig. 1. The iron crystals (iron 99.97, carbon 0.0012, nitrogen 0.0016 per cent by weight) were grown by strain annealing and were cooled from 890° C in a furnace. The polycrystalline iron was furnace-cooled from 790° C. Both kinds of specimens were from stock and had been stored at room temperature for 4 yr. The iron-silicon crystal was of similar purity and was grown by cooling from the melt at 200° C/h.

The actual strain rate¹ in the pre-yield region was 1.7×10^{-5} sec⁻¹. Test pieces had an electrolytically formed gauge section with 4BA threads at each end. The relaxation of the machine is negligible, as is that of the threads of polyerystalline test pieces near the yield stress. It is unlikely that the relaxation of the threads with single crystal specimens is significantly different.

In Fig. 1 the stress drop resulting from relaxation is plotted against the increasing stress at which the tensile machine was stopped; where straining to the same

stress was used, the numbers indicate the sequence in which load drop values were obtained. Unlike polycrystalline specimens, single crystals do not show a period without load drop followed by sudden yielding; instead, the load drop on relaxation increases up to and through the usual yield stress (with a rapid increase near yield for iron-silicon). Repeatedly reloading crystals to the same stress just below the yield point only slowly reduces the stress drop on relaxation, in contrast with the behaviour of polycrystalline material, where the stress drop rapidly decreases (until the post-yield Lüders region is reached).

The behaviour of the single crystals accords with the view that: (i) in high purity iron and iron—silicon crystals, there are always dislocations which can move at stresses below the yield stress and which are either lightly pinned dislocations or dislocations produced at some favoured source; and (ii) at the yield stress these dislocations are able to multiply rapidly and produce general yielding. The results suggest a large increase in mobile dislocation density in the pre-yield region and this is borne out by normal tests on iron crystals, which demonstrate a decrease of the slope of the stress-strain curve before the abrupt decrease at the yield point. Because pre-yield relaxation is little reduced on reloading after relaxation to the same stress, it follows that although dislocations effectively come to rest during relaxation, the movement of dislocations readily starts again with increasing stress. By contrast, mobile dislocations in polycrystalline material are probably prevented from multiplying rapidly by grain boundaries, and multiplication is difficult to restart after relaxation, so that the movement of dislocations is much reduced when loading is begun again.

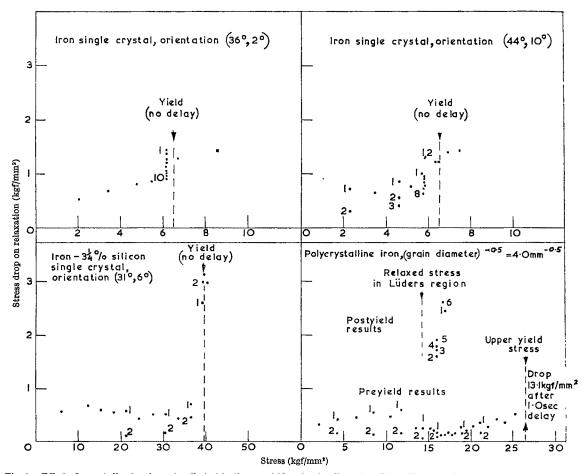

Fig. 1. Effect of repeatedly stopping a tensile test in the pre-yield region to allow relaxation. The stress drop resulting from relaxation is plotted against the increasing stress at which the tensile machine was stopped. Sometimes, after relaxation, the stress was increased to the same value as before relaxation; this was done as many as ten times, and the figures indicate the sequence of stress drop values for these cases.

repeated pre-yield relaxation in polycrystalline material, general yielding at the usual upper yield stress only obtains if either new dislocations (or dislocation sources) are unlocked, or if some critical amount of movement is attained in part of the dislocation network in yielded grains. This requirement leads to the observed delay before sudden yield.

I wish to thank D. E. Meyer for his assistance.

CHEMISTRY

Absolute Configuration and the Structure of Chlorophyll

THE structure of chlorophyll is known in considerable detail. The correct gross structure was put forward by Hans Fischer¹ and confirmed in a beautiful synthesis by R. B. Woodward^{2,3}; the relative configuration of the methyl and propionic ester groups on ring D was shown to be trans by Ficken, Johns and Linstead4; the stereochemistry and absolute configuration of the phytyl group was shown by Burrell, Jackman and Weedon^{5,6} to be 2^{r} -trans-7'R,11'R; and the relative configuration at C₁₀ was shown very recently by Wolf, Brockmann, Biere and Inhoffen^{7,8} to be that in which the methoxycarbonyl group is trans to the propionic ester side chain on C₇. (A recent review mentions the first X-ray crystallographic structure determination of a chlorophyll derivative, phyllochlorin ester. Success has come late in this field, because of disordered structures in the crystals of chlorophyll derivatives. The review gives no information about the absolute configuration.) The absolute configuration at C_7 and C_8 , however, was not known and there were therefore two diastereoisomeric structures still possible for chlorophyll. This report provides the missing information and completes the structure of chlorophyll-a (and therefore of chlorophyll-b) the configuration of which has been shown to be the same as that of chlorophyll-a).

In their work on the relative configuration of the groups on ring D, Ficken, Johns and Linstead⁴ oxidized phacophorbide-a and obtained (-)-trans-dihydrohaematinimide, (1) or (2), with $[\alpha]_{0}^{25^{\circ}}-46^{\circ}$, which they characterized as its benzylamine salt.

I have prepared the optically active imides (1) and (2) by resolution of synthetic, racemic imide¹¹ using the salt with (-)- α -methylbenzylamine¹² (for the (+)-imide) and with (+)- α -methylbenzylamine (for the (-)-imide). The (+)-imide had $[\alpha]_D^0+67^\circ$, which indicates that Linstead's sample had suffered a little racemization. The (+)-imide was hydrolysed to (+)-trans-dihydrohaematinic acid which crystallized (Linstead, no doubt partly because of the slight racemization, failed to obtain crystalline, optically active acid). The (+)-acid was converted into its tri-p-bromophenacyl ester, melting point $108.5^\circ-109^\circ$ C which was laevorotatory. I have prepared the enantiomer of this tri-p-bromophenacyl

ester from (-)- α -santonin (3) by the route illustrated, the chemistry of which need not be elaborated here. was because the acid (-)-(9), as prepared, was too impure to crystallize that the preparation of the tri-p-bromophenacyl esters was necessary. The derivative was separated from the other products of the ozonolysis by careful preparative thin-layer chromatography and obtained in very low yield but pure after one recrystallization. It was identical in melting point, infrared spectrum, thin-layer chromatographic behaviour and magnitude but not sign of rotation with the ester obtained before. When the esters (+)-(10) from santonin and (-)-(10) from the (+)-imide were mixed in equal quantities and recrystallized, pure racemic ester was produced, melting point 119°-120° C, identical in melting point, mixed melting point and infrared spectrum with an authentic sample prepared from racemic trans-dihydrohaematinic acid.

Because (-)- α -santonin has been shown with unusual thoroughness13-18 to have the structure and absolute configuration illustrated in (3), it follows that the (+)-imide has the absolute configuration (2). Because the (-)-imide is obtained from chlorophyll the absolute configuration of chlorophyll corresponds to that in the imide (1).

Chlorophyll-a therefore has the configuration 7S, 8S, 10R, 7'R, 11'R, and the structure (11).

Experimental details and a proof that two separate inversions, which could have led from santonin to the mirror image of (10), had not taken place will be published elsewhere.

BIOCHEMISTRY

Evolution of Protamine: a Further Example of Partial Gene Duplication

Partial gene duplication has been suggested as an important mechanism in the evolution of proteins1 on the basis of a study of the repeating structure of the light $(\alpha -)$ chain of the human haptoglobin molecule controlled by the Hp^2 gene. Support for this hypothesis has come from the discovery in several unrelated proteins of homologous sequences of amino-acids. In ferredoxin from Clostridium pasteurianun, portions of the N-terminal and C-terminal halves are homologous2 and these halves of the molecule may have arisen by partial gene duplication from an intermediate nonadecapeptide which in turn could have been derived by the same processes of duplication from an archetypal tetrapeptide^{2,3}. Other examples of internal homology have been postulated in cytochrome C (ref. 3), the haemoglobin chains4 and the light and heavy chains of immunoglobins.

We wish to propose a mechanism for the evolution of the clupeines. the protamines of the Pacific Herring (Clupea pallasi), through a series of partial gene duplications indicated by the observed internal homologies in the molecules. When the three polypeptides (YI, YII and Z) are aligned as in Table I, they are seen to be closely related. The differences can be explained by the genetic mechanisms of amino-acid insertion, deletion and replacement by single base change⁹. Clupeines Z and YII are related by three mutational events, Z and YI by eight, and YI and YII by eleven. In the evolution of the clupeines an initial divergence of the Z and YI sequences after a complete gene duplication appears to have been followed by a more recent divergence between the Z and YII sequences by the same mechanism10.

Examination of the sequences of the clupeines shows a repeating occurrence of the sequence Neu-Arg-Arg-Arg-Arg where Neu is a neutral amino-acid. If protamine has evolved from such an ancestral pentapeptide the codons' of the neutral amino-acids occurring in the first position favour the ancestral sequence Ala-Arg-Arg-Arg-Arg. A more comprehensive examination for internal homology was carried out using a computer programme similar to that described by Fitch¹¹. By this means all pentapeptide sequences which are related by one or less base changes were obtained. This value is considerably lower than that required in a similar examination of the haemoglobin chains because the clupeines are small molecules with a

Table 1. SEQUENCES OF HERRING SPERM PROTAMINES (CLUPEINES)6-8 Clupeine YI Ala-Arg-Arg-Arg-Arg-Ser - - Ser-Ser-Arg-Pro-Ile-Arg-Arg-Arg-Arg Clupeine Z Ala-Arg-Arg-Arg-Arg-Arg-Arg-Arg-Ala-Ser-Arg-Pro-Val-Arg-Arg-Arg-Arg Clupeine YII Pro-Arg-Arg-Arg — Thr-Arg-Arg-Ala-Ser-Arg-Pro-Val-Arg-Arg-Arg-Arg ${\bf Pro\text{-}Arg\text$ \mathbf{z} Pro-Arg-Arg - Val-Ser-Arg-Arg-Arg-Arg-Ala - Arg-Arg-Arg-Arg

high arginine content. For elupeine \mathbf{Z} , the average number of base changes for a random comparison of pentapeptide sequences is 3.5, whereas the corresponding figure for the Of the three clupeines, haemoglobin chains is 7.25. clupeine Z showed the greatest degree of internal homology and these homologous sequences, represented as two series of overlapping pentapeptides, and their relationship to the complete clupeine Z polypeptide chain are indicated

On the basis of these findings it is possible to propose several models for the evolutionary pathway from the ancestral polypeptide Ala-Arg-Arg-Arg-Arg to clupeine Z, and the one which seems to involve the minimum number of mutational events is presented in Fig. 2. We propose that there have been four successive partial gene duplications of different lengths. The first duplication was of five residues (Ala-Arg-Arg-Arg-Arg) leading to a decapeptide, and the second duplication involved a sequence of eight residues (Ala-Arg-Arg-Arg-Arg-Ala-Arg-Arg) and resulted in an octadecapeptide. In the next step the chain is shown in Fig. 2 as being lengthened by a

single Ala at position 9 or 10 as a result of a partial duplication limited to one residue. There is another alternative for this step, that is the second duplication could have been of nine residues leading to a nonadecapeptide followed by a two step mutation at position 9 from Arg to Ala (ref. 9). It is not possible to assess the relative probabilities of these two mechanisms. After this Ser could be obtained from Ala at position 10 by a single base change. A fourth duplication, this time of twelve residues (Ala-Arg-Arg-Arg-Arg-Ala-

Arg-Arg-Ala-Ser-Arg-Arg), could then have occurred and the full length (thirty-one residues) of present day clupeine Z would have been reached. The resultant polypeptide differs by only five single point mutations from elupeine Z, at positions 6, Ala-Ser, 12, Arg-Pro, 13, Ala-Val, 18, Ala→Pro and 21, Ala→Val, all of which can occur by a

single base change within the coding triplet.

Before the occurrence of this last single base change (position 21) a complete gene duplication could give rise to the ancestral clupeine YI which then evolved by single base changes at position 9, Ala—Ser, 13, Val—Ilc, 21, Ala-Thr, the deletion of Arg-Arg, 7 and 8, and the insertion of Arg between positions 20 and 21 and Gly between positions 27 and 28 to give rise to present day clupeine YI. Clupeine YII can be derived from clupeine Z by the deletion of an Arg between positions 2 and 5 and two single point mutations at positions 1, Ala-Pro, and 6, Ala-Ser.

Three of the possibly significant comparisons shown in Fig. 1 have not been used in this evolutionary pathway. These are considered to be a consequence of the high arginine content and small size of the clupeines, which

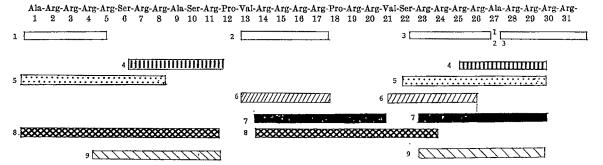

Fig. 1. The relationship of segments of amino-acid sequence of clupeine Z which were determined by a computer comparison to show significant homology. Segments indicated by the same number (and similar shading) are related by less than 0·2 base changes/amino-acid codon. Segments 4, 6 and 9 were not used in deriving the evolutionary pathway proposed in Fig. 2 for the reasons discussed in the text.

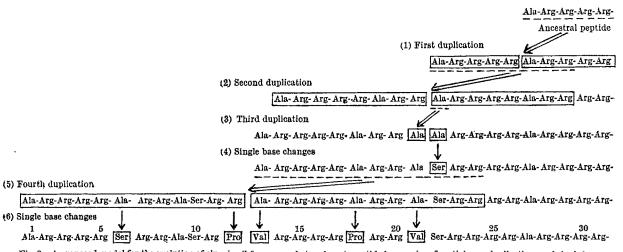

Fig. 2. A proposed model for the evolution of clupsine Z from an archetypal pentapeptide by a series of partial gene duplications and single base changes in the structural gene for this protein. The segment of polypeptide underlined corresponds to that portion of the structural gene which is partially duplicated and the resulting new polypeptide sequence is enclosed in a box. Single arrows represent single base changes while the double arrows show the partial gene duplications.

mean that a statistical search for homology will yield a proportion of comparisons which are not in accordance with any proposed pathway. The evolutionary pathway which we propose is based not only on the small number of base changes involved in each comparison but also on the minimal number of mutational events required to obtain the present day clupeines from the ancestral pentapeptide Ala-Arg-Arg-Arg-Arg.

Kinetics of RNA Labelling in Fractions enriched with Neuroglia and Neurones

THERE are now methods of separating in bulk neuronal and neuroglial cells1,2, and we have used them to study the in vivo synthesis of RNA in these cellular fractions. There seem to be significant differences between the kinetics of labelling of the RNA of the two cell types.

6-14C-orotic acid (44.5 mc./mmole) was given subarachnoidally to adult rabbits weighing 3-4 kg in a dose of 100 $\mu c.$ in 0.2 ml. RNA was extracted with a mixture of sodium dodecyl sulphate and phenol at 4°, followed by re-extraction of the phenol phase and interphase at 45° C, digested with DNase and analysed by centrifugation in 5-20 per cent sucrose gradients containing 0·1 molar sodium chloride and 4 molar urea (15 h at 20,000 r.p.m. in the SW25 rotor of a Spinco ultracentrifuge at 0°-4° C). The results are summarized in

One hour after the injection of the precursor neuronal RNA had a lower specific activity than neuroglial RNA, while after 3-6 h it was much more heavily labelled. These differences were more clearly seen in the cellular fractions prepared by the method of Satake and Abe² (Fig. 1a and b). Some of the most obvious differences were observed in the RNA fractions which sedimented before the 28S peak. These fractions represent a mixture of pre-ribosomal components and of DNA-like nuclear RNA of unknown function³ which is synthesized more rapidly than the other types and is more rapidly degraded4,5. The relative composition of neuronal RNA rich in the ribosomal species and of glial RNA rich in the nuclear components may be the basis of the different kinetics of labelling which we observed. Other explanations, however, cannot be excluded.

Fourteen hours after administration of labelled orotic acid the specific activity of neuronal RNA prepared by the method of Satake and Abe² decreased considerably with little concomitant change in the specific activity of the RNA extracted from the heterogeneous non-neuronal fraction (Fig. 1b). This might be explained by migration of neuronal RNA into cellular compartments not recovered with the nerve cell bodies, such as axons and nerve endings. The corresponding increase in the

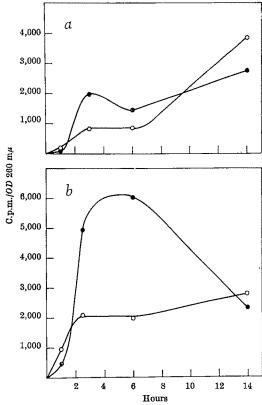

Fig. 1. Kinetics of labelling of total RNA in fractions enriched with neurones (a) and neuroglia (5). (a) Method of Rose; (b) method of Satake and Abe. Optical densities and radioactivity refer to data obtained by integration of sucrose gradient patterns.

specific activity of neuroglial and to a smaller extent neuronal RNA prepared by the method of Rose¹ (Fig. 1a) might reflect contamination of these fractions with such particulates.

Evidence for the Random Aggregation of Sub-units to produce Multiple Forms of Lactate Dehydrogenase in the Brains of Rat and Man

LACTATE dehydrogenase (LDH) activity is present from the earliest stages of animal development and has been detected in the oocytes of both vertebrates1 and invertebrates2. It is now recognized that the enzyme is composed of two types of sub-unit3, with separate structural genes4, which probably combine randomly into tetramers forming the five electrophoretically distinct forms, H_4 , H_3M , H_2M_2 , These have been numbered LDH-1 to 5, respectively, with LDH-1 being the most electropositive.

The proportions of the LDH forms have been observed to change during the development of various tissues from rat⁵, chick^{6,7}, rabbit⁸ and human^{5,9}, which suggests that the two structural genes are under independent although possibly linked control. Attention has been directed chiefly towards liver and skeletal muscle in which the proportions of the more slowly migrating, M-containing enzyme forms increase during development, and towards heart where the proportion of H-sub-units increases during development.

In adult brain LDH-1 to 3 appear to be the dominant forms^{7,10-13} although a comparison of various primates shows that this is not always the case¹⁴. We have studied the developmental changes in the lactate dehydrogenases of rat brain between day 16 of gestation and 18 days post-partum, and human brain between 5 weeks and 20 weeks of gestation. The human foetuses were obtained either by surgical induction or from spontaneous abortions. As soon as the tissues became available they were homogenized in ice cold isotonic saline (0.5 g/2 ml.) and analysed by horizontal starch gel electrophoresis using the discontinuous buffer system of Poulik16. The enzyme was stained with a mixture of NAD+, sodium lactate, phenazine methosulphate and nitro blue tetrazolium16 and quantitative estimates of the colour intensity in the gel were made with a Joyce 'Chromoscan' reflectance densitometer with integrator using a yellow-brown filter (Joyce 5021). Preliminary experiments determined the range over which intensity of reduced nitro blue tetrazolium in the gel was proportional to lactate dehydrogenase activity. In both rat and human, the enzyme patterns in cerebrum and cerebellum were the same at all the stages of development we investigated.

Rat brains from foetuses of 16 days gestation and older showed all five LDH forms (although under the conditions of electrophoresis used LDH-5 often lay partly within the origin). At 16 days LDH-5 is the most prominent form and LDH-1 the least prominent. Up to parturition LDH-5 progressively decreases to about 10 per cent of the original value while LDH-1 increases slightly (Fig. 1). LDH-2 and 3 also increase but LDH-4 decreases slightly. By about 14 days post-partum the proportion of the five forms is close to the 1:3:6:3:1 ratio expected from random association when H and M-type sub-units are being synthesized in equal amounts (Fig. 1). In the adult rat brain (Fig. 2), there is slightly more LDH-1 and 2 and less LDH-5, suggesting that the H-type sub-units are being synthesized faster than the M-type sub-units.

In contrast to the rat, the human brain presents a very static pattern of LDH forms from 5 weeks gestation, at which point the neural tube is not completely closed, up to 20 weeks—the maximum age at which foetuses were obtainable—and is quite similar to that of the adult (Fig. 3). Over this period the ratio of the five forms is very close to 1:3:6:3:1 (Table 1) suggesting that both sub-units are being produced in equal amounts and then

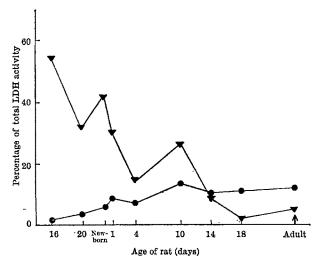

Fig. 1. Time course of the change in concentrations of LDH-1 (●——●) and LDH-5 (▼——▼) in the developing rat brain.

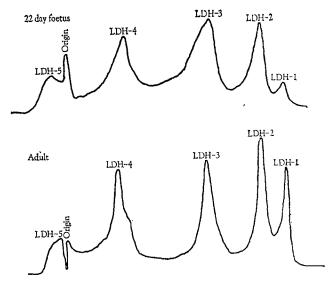

Fig. 2. Comparison of densitometer tracings of the multiple forms of lactate dehydrogenase from adult and 22 day foctal rat brain to show the relative increase in LDH-1 with increasing maturity.

combining in a random manner. There seems to be a slight change between 20 weeks and adulthood, however, when the concentration of LDH-1 increases about two-fold and LDH-5 and 4 fall to lower levels. This latter change was found to be rather variable and may possibly reflect the inevitable delay between death and obtaining samples. LDH-1 is very labile and considerable activity

Table 1. PROPORTIONS OF THE MULTIPLE FORMS OF LACTATE DEHYDROGENASE IN DEVELOPING HUMAN BRAIN

					Mean	1.13	3.1	5-6	$3 \cdot 2$	1.0
Adult	17	28	42.5	11.5	1	2.4	3.9	5.9	1.6	0.1
Adult	15	30	40	15	0	$2 \cdot 1$	$4\cdot 2$	5.5	$2 \cdot 1$	0

is lost by overnight storage in the refrigerator. Indeed, Latner and Skillen⁹ were unable to detect any LDH-1 and 2 in foetal brain while Pfleiderer and Wachsmuth¹² found a higher proportion of LDH-1 in adult and foetal brains than any recorded in our experiments.

In conclusion, the developmental patterns of brain lactate dehydrogenase are quite different in the rat and the human, and the human resembles the chicken' more than it does the rat. Whether or not there is any significance in the developmental patterns in terms of enzyme function, as has been suggested in relation to muscle activity¹⁷, is not at present clear. The results are in accord with the inference⁵ that the multiple forms of lactate dehydrogenase arise by random aggregation of the H- and M-type sub-units.

Effect of Alloxan Diabetes, Starvation and Refeeding on Glycolytic Kinase Activities in Rat Epididymal Adipose Tissue

THE levels of glucokinase, phosphofructokinase (PFK) and pyruvate kinase (PK) in the liver are decreased in alloxan diabetes and starvation, and are increased on refeeding¹⁻³. Weber $et\ al.$ have postulated that glycolysis may be, at least partially, controlled by the synchronous induction and repression of these regulatory enzymes through the action of hormones on a "functional genome" 4. Changes of similar magnitude have not been observed in the heart with hexokinase (HK) (ref. 5) and PFK (ref. 6), but in epididymal fat pad, HK activity is markedly affected by these conditions^{7,8}. The observed sensitivity of the PK in the fat pad to the allosteric effector fructose 1,6-diphosphate (Pogson, unpublished results), and the known kinetic properties of the PFK in the fat pad, support the suggestion that these enzymes are of significance in the control of fat pad glycolysis. In view of these findings, it seemed important to determine whether the levels of all three kinases were responsive to conditions of alloxan diabetes, starvation and refeeding.

Chemicals were obtained from sources described previously^{10,11}. All enzymes were obtained from Boehringer Corporation (London), Ltd. Male albino Wistar rats (150-200 g) were used throughout and the diet, unless otherwise stated, was as given by Newsholme and Randle¹². Acute alloxan diabetes was induced by intravenous injection 48 h previously of 60 mg of alloxan/kg. High blood sugars (>300 mg per cent) were confirmed with

'Dextrostix' (Ames Co., Slough). In the starvationrefeeding experiments, animals were starved for 3 days, then fed for a further 3 days on a powdered diet consisting of one part fat free milk extract (J. Sainsbury, Ltd.) and two parts castor sugar; controls were fed a powdered normal diet for the first 3 days and then high carbohydrate diet.

Rats were killed by decapitation. The pairs of epididymal fat pads were rapidly excised, washed briefly in the extracting buffer at 22° C, blotted gently, weighed and extracted once with 3 vol./g of 50 mmolar tris-acetate buffer, pH 7.4, containing 50 mmolar magnesium sulphate and 2 mmolar EGTA (ethylene glycol-bis (2-aminoethyl)tetraacetate) in a hand-operated glass Potter-Elvehjem homogenizer at 0° C. The homogenates were centrifuged at 2,800g for 20 min at 2° C, and the supernatants were then decanted and kept at 0° C.

All enzymes were assayed in the supernatants within 8 h of extraction by following the changes in extinction at 340 mµ through a 1 cm light path in a Hilger-Gilford recording spectrophotometer at 25° C. In all cases, activity was measured in 50 mmolar tris-acetate buffer, pH 7·4, containing 50 mmolar potassium chloride, 15 mmolar potassium sulphate and 5 mmolar magnesium sulphate; final volume 3.0 ml. HK was assayed by following NADP reduction in the presence of 10 mmolar glucose, 5 mmolar ATP and excess glucose-6-phosphate dehydrogenase; PFK by following NADH oxidation in the presence of 1 mmolar glucose-6-phosphate, 2 mmolar ATP and excess phosphoglucose isomerase, aldolase, triosephosphate isomerase and α-glycerophosphate dehydrogenese; and PK by following NADH oxidation in the presence of 1.5 mmolar phosphoenolpyruvate, 2 mmolar ADP, 0.3 per cent bovine serum albumin and excess lactate dehydrogenase. In addition, as a control activity, aldolase was assayed in a similar medium containing 2 mmolar fructose-1,6-diphosphate and excess triosephosphate isomerase and α-glycerophosphate dehydrogenase. One unit of kinase is defined as that amount catalysing the formation of 1 µmole of product/min at 25° C. One unit of aldolase is taken as the amount catalysing the disappearance of 1 µmole of fructose-1,6diphosphate/min at 25° C.

Preliminary control experiments demonstrated that all activity is extracted by this procedure, that enzyme activities in supernatants remain unchanged during the course of experiments and that maximal activities are obtained with the substrate concentrations stated previously. Simultaneous blank determinations were carried out for PFK (minus glucose-6-phosphate) and aldolase (minus fructose-1,6-diphosphate); NADH oxidase activities were about 10 per cent and 1.5 per cent, respectively. PK blanks were insignificant; in HK assays added NADPH was not oxidized. For calculation of the HK activity, we assumed that 2 moles of NADP were reduced for each mole of glucose phosphorylated, because (a) extracts contained 6-phosphogluconate dehydrogenase in excess of HK activity, and (b) rates in HK assays were not increased by addition of a 1,000-fold excess of purified 6-phosphogluconate dehydrogenase. Protein concentrations were determined by the method of Lowry et al.13, with bovine serum albumin as standard.

The results of these experiments are given in Table 1. The differences shown in enzyme activities between control rats in alloxan diabetic and starvation-refeeding experiments may be attributed to variations between batches of animals from different sources. Activities are expressed in terms of units per fat pad pair and per mg protein; results expressed in terms of tissue weight are misleading in that the reduction in fat pad weight in alloxan diabetes and starvation may be largely attributed to fat mobilization under these conditions. The lowest activities in the normal rats are those of HK and PFK, which varied in different experiments from 9.7 to 36.4 mu/mg protein and 15.8 to 48.4 mu/mg protein, respectively.

compare with maximum uptakes of glucose in fat pads from rats fed normally on approximately 10 mumoles/mg protein/min, as calculated from known data¹⁴. Total HK activity is decreased approximately 40 per cent in alloxandiabetes and starvation. These figures are in close agreement with previously published data7,8. In contrast to the changes in HK, levels of PFK, PK and aldolase are not depressed to any statistically significant extent. Refeeding after starvation restores HK activities to control values in experimental animals. The levels of both HK and PK in the controls fed the high carbohydrate diet are markedly increased over those of the controls on the normal diet, while smaller changes are apparent in PFK and aldolase activities. The physiological importance of the changes in HK activity in epididymal fat pad have been considered previously^{7,15}. Ballard et al. 16 have recently reported the occurrence of phosphoenolpyruvate carboxykinase in this tissue, and have demonstrated the conversion of pyruvate to glyceride-glycerol through the dicarboxylate shuttle. It is most probable therefore that PK has a regulatory role in determining the fate of phosphoenolpyruvate in fat pad. The changes observed with high carbohydrate diet are consistent with this hypothesis, and may thus be of some physiological significance.

Fatty Acid Ester-Hydrocarbon Correlation Trial: a Comment

DURING the sixth International Symposium on Gas Chromatography in Rome¹, Dr P. A. T. Swoboda, on behalf of the Data Sub-committee of the Gas Chromatography Discussion Group, presented a preliminary report on an inter-laboratory trial on the reproducibility of retention data, which gave the following conclusion: "... the use of the carbon number scale leads to a high degree of agreement between laboratories for the methylesters of unsaturated fatty acids. In contrast there is a wide variation for the hydrocarbons. Thus the use of a secondary series of standards (such as the methylesters of the n-alkanoic acids) as the basis for a logarithmic scale of retention gives a higher inter-laboratory precision for measurement of compounds of similar structure than would be obtained by using the Retention Index based on the n-alkanes".

In my opinion the data presented do not justify this conclusion. Only esters have been compared with hydrocarbons and extension of the generalization to other classes of compounds does not seem justified without more data.

Another point to be considered is the stationary phase used (polyethylene glycol adipate, PEGA). Each participant used his own batch of PEGA and the reporter observed that the results of participants whose PEGA was either too polar or too apolar were not included in the analysis. Moreover, no mention is made of the amount of stationary phase nor of the support used. I feel that this indicates that different batches of PEGA differed in polarity or at least that the total columnpackings differed in polarity. Furthermore, PEGA is also an ester and hence similar to the compounds chromatographed.

In my opinion, the wide range of carbon numbers, as displayed by the n-alkanes, reflects the differences in polarity between the column-packings, this reflexion being less for the esters because of the similarity between the solutes and solvent (PEGA).

I should also like to comment on the way the carbon numbers were calculated. It is formally stated that "the algebraic equation defining the scale is the same as that used for the calculation of Retention Index". For the calculations, however, a straight line was fitted statistically instead of using the actual measurements. In the case of the n-20-alkane even extrapolation was used. This method of calculation introduces an error unnecessarily. Although the statistical procedure permits confidence limits to be drawn, no such limits are mentioned. In view of the fact that in the equation given in the report, both constants are related, I believe that in fact $r_{x_{17}}$ values, not carbon numbers, were determined.

Apart from the comment on the calculation, my principal point is that there is a need for some kind of characterization of columns with respect to "polarity", especially in trials of this kind.

Influence of Acute and Chronic Administration of Alcohol on Carbohydrate Breakdown and Energy Metabolism in the Liver

AFTER a single dose of ethanol, changes in the contents of metabolites of the Embden-Meyerhof glycolytic pathway in the liver, which indicate that the degradation of carbohydrates through the first steps of this pathway is accelerated, can be observed. These changes are caused partly by the effect of catecholamines (unpublished work), which are liberated in excess from the adrenals1-4, and partly by the enhanced formation of reduced nicotinamide-adenine dinucleotide (NADH₂) during the oxidation of ethanol⁵. Until now the influence of a prolonged intake of alcohol on the metabolites of carbohydrate breakdown and energy metabolism has not been investigated. Because we thought that there might be differences in the effects of ethanol after acute and chronic administration, as a consequence of adaptational processes, we investigated the contents of glycogen, glucose, glucose-6-P, fructose-1·6-P₂, dihydroxyacetone-P, glycerol-1-P, pyruvate, lactate and ATP in the livers of animals which over a period of 6 months had received a 15 per cent solution of alcohol instead of drinking water.

To study the effect of a sudden withdrawal of ethanol on the metabolite contents of the liver of animals which have been adapted to alcohol, we treated animals with ethanol for 6 months and determined the metabolite contents of the liver 4 h after the alcohol had been withdrawn. At this time alcohol in the blood was no longer detectable.

detectable.

All experiments were carried out at an environmental temperature of 24° C on female NMRI-mice which had free access to a standard diet (Altromin R; Altromin GmbH, Lage/Lippe, Germany) before and during the experiments.

One group of animals was intravenously injected with 1.5 mg/g ethanol and the metabolite contents in the liver were estimated 30 min later. A second group of animals received a 15 per cent (w/v) solution of alcohol ad lib. instead of drinking water for 6 months. The animals were then killed to determine the metabolites in the liver. A third group of animals was treated with ethanol in the same manner as the second group, but 4 h before the animals were killed the alcohol was withdrawn and replaced by tap water. Groups of untreated animals of the same age served as controls.

In order to investigate the metabolites in the liver, the animals were killed by immersing them in liquid air, and the livers were removed while still frozen. Blood was collected from animals which were killed by decapitation. The analytical procedures for the assay of bloodalcohol, glycogen, glucose, glucose-6-P, fructose-1-6-P₂, dihydroxyacetone-P, glycerol-1-P, pyruvate, lactate and ATP were the same as described in previous papers^{5,6}. Mean values and their standard errors were calculated from 10–15 individual values. The results were checked by the Student's t test and differences between two mean values were regarded to be significant if $P \leq 0.05$.

Thirty minutes after the intravenous injection of 1.5 mg/g ethanol, the blood alcohol level was 2 %/00. Glycogen, glucose and pyruvate contents in the liver had decreased; fructose-1.6-P2, dihydroxyacetone-P and glycoerol-1-P had increased, while the contents of glucose-6-P and lactate had not changed significantly. The decrease of the glycogen content is regarded as the result of an enhanced glycogen breakdown caused by the effect of catecholamines which are mobilized from the adrenal medulla by alcohol¹⁻⁴. The increase of fructose-1.6-P2 and dihydroxyacetone-P points to an accelerated degradation of carbohydrates through the first steps of the glycolytic pathway. The enhanced formation of NADH2, resulting from the dehydrogenation of ethanol, promotes

the conversion of dihydroxyacetone-P to glycerol-1-P, a reaction in which NADH, is oxidized. On the other hand, the oxidation of 3-phosphoglyceric aldehyde to 1.3diphosphoglyceric acid, which is linked with the reduction of NAD to NADH2, is probably reduced. This is indicated by the low level of pyruvate, which forms the final product of this metabolic chain. It must be remembered, however, that the pyruvate content may also be lowered as a result of the raised ratio of NADH2 to NAD in the cytoplasm, which promotes the conversion of pyruvate to lactate. According to Bücher and Klingenberg⁷, shifts in the NADH₂ to NAD ratio are indicated by the ratios of glycerol-I-P to dihydroxyacetone-P and lactate to pyruvate.

The excess glycerol-1-P that is formed is required for the synthesis of triglycerides, which is enhanced under the influence of alcohol⁸, as well as for the transport of hydrogen, which is derived from the oxidation of ethanol, from the cytoplasm into the intramitochondrial compartment7. The more than 2.5-fold increase of glycerol-1-P shows that the synthesis of glycerol-1-P by far exceeds the requirements.

After prolonged intake of alcohol for 6 months, the food consumption of the mice decreased from 137 ± 9 to 84 ± 8 mg/g body weight/day and liquid consumption decreased from 0.139 ± 0.005 to 0.079 ± 0.003 ml./g body weight/day. Blood alcohol levels were found to be between 0.8 and $1.8~^{\circ}/_{\circ \circ}$ depending on the hour of the day. In the liver only the glycerol-1-P content was elevated and only glucose and glucose-6-P contents were decreased. contents of the other metabolites investigated did not differ significantly from their control values. The decrease of glycogen content, found after a single dose of alcohol, cannot be observed in the chronically treated animals. This finding, which contrasts with the results of Mirone⁹, may be caused by an adaptation of the rate of glycogen formation to glycogen breakdown. The decrease of glucose and glucose-6-P content in the liver, while fructose-1.6-P2 and dihydroxyacetone-P remain unchanged, suggests that the first steps of the glycolytic pathway are accelerated in chronically treated animals as well as in animals which have had a single dose of ethanol. Though there was no rise in the fructose-1.6-P2 and dihydroxyacetone-P contents, the glycerol-1-P content was still elevated. Just as in the acute experiments this is probably due to the increased supply of NADH₂.

In contrast to the results in acutely treated animals, there is no evidence that in chronically treated mice the rate of glycolysis is slowed down between dihydroxyacetone-P and pyruvate. This suggests that in the enzyme systems involved adaptative changes have taken place which ensure a sufficient supply of pyruvate in spite of the increased formation of glycerol-1-P and a high NADH₂ to NAD ratio.

Four hours after the withdrawal of the ethanol it was found that the ethanol had disappeared from the blood. This causes a fall of the elevated NADH2 to NAD ratio

as indicated by the glycerol-1-P to dihydroxyacetone-P and lactate to pyruvate ratios. Thus the formation of glycerol-1-P is greatly reduced and the glycerol-1-P content falls to about 60 per cent of the control values. At the same time excess pyruvate is formed probably on account of glucose-6-P, fructose-1.6-P2 and dihydroxyacetone-P, the content of which is decreased. This may be due to a rebound of the glycolytic enzyme systems which were formerly under the control of the high NADH2 to NAD ratio. In this way, our results show once more the important part that is played by the redox status of the cytoplasmatic NAD for the regulation of the glycolytic pathways.

After a single intravenous injection of 1.5 mg/g ethanol there was a small but insignificant rise in the ATP content of the liver, whereas the ATP content decreased after chronic administration of alcohol. The ATP content remained low after the withdrawal of the alcohol. It appears that chronic ethanol intake leads to a derangement of ATP synthesis, which persists at least 4 h after the withdrawal of the alcohol. The derangement of ATP synthesis is believed to be an expression of a functional cellular damage which outlasts the direct toxic effect of ethanol itself.

BIOLOGY

Optimization of the Genetic Code

THE Atlas of Protein Sequence and Structure compiled by Eck and Dayhoff¹ provides an opportunity for preliminary statistical examinations of aspects of the genetic code.

Taking twenty-five different proteins—admittedly not a random sample representing their natural occurrence-I have found the following frequencies for the twenty amino-acids

Asn 108 Arg 104 Pro 99 Asp 94 Ilu 90 Glu 86 Phe 86 Gln 78 Cys 76 Ser 218 Ala 183 Gly 166 Leu 158 Val 153 Lys 145 Thr 142 + (presumably) 25 terminators 2,196

29 Gix (= Glu or Gln), 26 Asx (= Asp or Asn) and 2 xxx (= unknown) have been excluded.

If these frequencies are plotted as a graph (to test whether, for example, a form of Zipf's law2 operates) two breaks, corresponding to the columns in which the data have been arranged here, are evident. The distribution is thus not to be represented by a simple function.

Using relative frequencies the data can be converted to a binary coding by Huffman's algorithm³. This algorithm allocates to each of the twenty-one categories a binary number such that the coding is optimum—that is, if information as to the sequences of a number of proteins, with the probabilities given here for the occurrences of the individual amino-acids, had to be sent over a telegraph circuit, this could be accomplished at the least cost. The coding procedure consists of the allocation of sequences of dichotomies using in turn pairs of categories which are nearly equi-probable. It has been shown that this procedure allocates binary digits so that the average number of bits in each category exceeds by less than one the optimum coding. In this communication, digram frequencies, transition probabilities, are neglected.

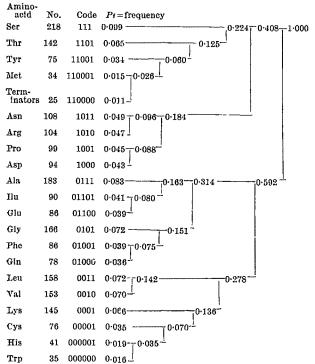

Table 1 shows the sequence of dichotomies and the resulting codings are given in the third column of Table 2. If all the codings were to be of the same length then they would have to contain five binary digits (and there would be 32-21=11 unused or nonsense codings). If the "negentropy" of the frequency distribution of amino-acids,

 $-\sum_{i=1}^{21} P_i \log_2 P_i$, is calculated, 3.97 bits in each category

is the absolute minimum required to code the twenty-one categories, neglecting interactions in higher order structure. In Table 2, column 4 gives the number of bits allocated to each category by the Huffman system (these numbers must be integers) and column 5, which gives the products of these numbers with the P_i , shows that the average number of bits in each category according to the Huffman algorithm is 4.257—only 0.29 higher than the theoretical minimum.

We now consider the way in which the twenty acids + terminator are coded by the natural genetic code of nucleotide triplets4. Each amino-acid is coded by a triplet of quaternary digits-U, C, A, G. There are thus (as described coincidentally in the early Chinese world system of the I Ching⁵) sixty-four different codons, each requiring six bits for its specification. Each possible codon but one has been allocated a provisional meaning. Serine, for example, is specified by each of six codons, so that the information content of a codon coding for serine is reduced by log₂ 6 bits from 6 to 3.4 bits. Similarly, if four codons code for alanine, the information content of one triplet coding for alanine is reduced to 4 bits. In

Table 1. RESULT OF APPLICATION OF HUFFMAN'S CODING ALGORITHM

inator	0.011	110000	6	0-066	2 (ochre amber) 1 (?)	5	0.055		
21	1.000			4.247	64		4.320		

Table 2, column 6 shows the number of bits used to code each category. Multiplying these numbers by P_t gives the average number of bits in each category in the naturally developed code as 4.320. This number exceeds the "negentropy" by only 0.35 bits. If the twenty-one categories were equi-probable and coded optimally, $\log_2 21 =$ 4.4 bits would be required.

The genetic code is degenerate, but the degeneracy is not evenly distributed. There is a correlation between the frequency of occurrence of an amino-acid and the number of triplets coding for it, precisely as in a commercial code book alternatives are provided for frequent words, so that these cannot be identified from the frequencies of their coded representations.

The natural genetic code, given the base triplet mechanism, thus approaches remarkably closely to the optimum coding. This observation seems of significance when considering the evolution of the code by natural selection.

Protective Immunity produced by the Injection of X-irradiated Sporozoites of Plasmodium berghei

STUDIES with avian malaria have shown that killed sporozoites as well as sporozoites inactivated with ultraviolet light can produce a partial immunity after injection into birds^{1,2}. On the other hand, attempts to use the erythrocytic stages of the parasite as the source of antigen have met with only limited success with avian3, rodent4 and monkey malaria^{5,6}. Previous attempts to use killed sporozoites of the rodent malarial parasite, Plasmodium berghei, to immunize rodents have been unsuccessful. We therefore sought to determine whether protective immunity to this parasite could be achieved by partial inactivation of the injected sporozoites as opposed to injection of dead parasites. X-irradiation was chosen as the inactivating agent, because of the partial immunity

obtained by vaccination with irradiated blood forms of malaria parasites⁷⁻⁹. This communication reports preliminary results on the production of protective immunity in mice by vaccination with X-irradiated sporozoites of P. berghei.

Sporozoites were obtained by dissection of the salivary glands of laboratory bred A. stephensi 14 days after feeding on a hamster infected with P. berghei. After homogenization of the salivary glands in 50 per cent human plasma diluted in saline, the suspension of sporozoites was irradiated in the 280 kVp X-ray beam of a Picker Vanguard teletherapy unit. The dose of radiation ranged from 2 to 15 krads. Irradiated parasites were injected intravenously into A/J mice, each mouse receiving between 5,000 and 75,000 sporozoites in an injection of 0.2 ml. In each experiment, a control group of A/J mice of the same age and sex was injected with non-irradiated sporozoites of the same pool to permit comparison with the infections produced by the irradiated parasites.

The amount of irradiation necessary to inactivate sporozoites sufficiently so that patent infection was prevented varied from 6 krads to more than 10 krads. The more viable the batch of sporozoites, the higher the dose of X-irradiation needed to produce this effect. A more detailed account of these experiments and additional data

will be published elsewhere.

Whether protective immunity resulted from the inoculation of irradiated sporozoites was determined by challenging those animals in which the injection of 5,000 irradiated parasites had failed to produce a patent malarial infection. These mice were challenged by intravenous injection with viable sporozoites (1,000/mouse) about 2 weeks after injection of the irradiated sporozoites.

The results indicate the presence of a certain degree of protection, for on challenge significantly less infection was observed in some groups of "vaccinated" animals, as compared with their controls. The best protection was conferred by sporozoites irradiated with 6, 8 or 10 krads. The degree of protection varied somewhat from experiment to experiment, and further data are needed to determine the relation, if any, between the dose of radiation and the degree of protection obtained.

More significant protection was observed when the immunizing dose, that is the number of irradiated sporozoites, was increased to 75,000/animal. This inoculum (75,000 sporozoites irradiated with 8 or 10 krads) was injected into forty-six mice, out of which only one developed a patent infection. All the remaining, apparently negative, animals were challenged with 1,000 viable sporozoites. The results are summarized in Table 1.

Table 1. VACCINATION WITH X-IRRADIATED SPOROZOITES OF P. berghei (75,000 SPOROZOITES/MOUSE)

Experi- ment No.	Cont No. : percent animals i	and age of	Day of challenge	Vaccinated a No. a percenta animals in	nd ge of	Protec- tion (per cent)

All control and vaccinated animals were challenged with 1,000 sporozoites

All control and vaccinated animals were challenged with 1,000 sporozoites injected intravenously.

Percentage protection was calculated as 100 percentage minus per cent of vaccinated animals which became infected, correcting this value for an assumed 100 per cent infection of controls.

* The sporozoites in this experiment were irradiated with 10 krads; 8 krads were used in all other experiments.

Experiments 5 and 6 were challenged simultaneously so that they had their control group in common.

† Most of these animals remained protected against a second challenge, 36 days after this vaccination (67 per cent protection).

Although the degree of protection varied from experiment to experiment, the overall protection rate may be expressed by the fact that only 37 per cent of the vaccinated animals became positive after challenge, as compared with 90 per cent of the controls.

In vaccinated animals which became positive after being challenged, the prepatent period as well as the survival time was usually longer than in the nonvaccinated controls, but all animals ultimately died from their malarial infection.

These results differ somewhat from the attenuated P. berghei infections obtained in rats and in rats and mice vaccinated with X-irradiated blood forms and challenged with the same stage of this parasite.

As for the protected animals, at least in one instance, they remained significantly resistant to a second challenge, 36 days after the initial inoculation. Further work to determine the duration of this protection and its possible enhancement by the administration of repeated doses of irradiated sporozoites will be reported elsewhere.

It has previously been observed that the natural nonspecific resistance of the host to sporozoite induced infection can be greatly enhanced by various means, such as the administration of Freund's adjuvant, or of dead Corynebacterium parvum10. In view of this, it was necessary to ascertain the possible non-specific effect resulting from the injection of relatively large amounts of mosquito salivary gland tissue.

Homogenized salivary glands from non-infected mosquitoes were irradiated and injected intravenously into The amount of gland material (salivary glands mice. from nineteen mosquitoes into each mouse) was equivalent to that injected during a vaccination with 75,000 sporo-These mice together with controls were latered with sporozoites. The mice injected with zoites. challenged with sporozoites. normal mosquito tissue not only were not protected but had an even more virulent infection than the controls, with a shorter prepatent period and a shorter survival One possible explanation for this accelerated time. infection would be the considerable reticulocytosis observed in these animals, which would tend to favour the P. berghei infection.

Animals vaccinated with 75.000 irradiated sporozoites showed no protection even against a relatively small inoculum of parasitized red blood cells (1,000). Also in this case, and possibly for the same reason indicated in the previous paragraph, there was a certain enhancement of the infection in the vaccinated animals as compared with their controls.

This protection thus seems to be stage specific to the extent that it does not alter the course of blood induced infection of the same strain of P. berghei, its effect being limited to the sporozoite stage. A similar stage specific protection has been reported in vaccination with sporozoites of avian malaria2.

We can summarize the results of our experiments as follows. The X-irradiation of sporozoites of P. berghei inactivated these parasites, in certain conditions, so that they no longer produced patent malaria infections detectable by blood smears in A/J mice. It was further shown that a large percentage of these vaccinated animals were protected against the injection of viable sporozoites. Thus, if a sufficiently large number of irradiated sporozoites was inoculated (75,000), only 37 per cent of these vaccinated animals became infected on challenge as compared with 90 per cent of their controls. In the rest of the vaccinated animals there was a certain delay of the infection, but its invariably lethal outcome was unaltered.

The protection obtained by injection of irradiated sporozoites was apparently limited to challenge with this stage of the life cycle of P. berghei, being without effect against the injection of blood stages of the same parasite. Likewise, the injection of comparable amounts of normal mosquito salivary glands failed to protect against sporozoite induced P. berghei infection.

This work was sponsored by the Commission on Malaria, Armed Forces Epidemiological Board. and was supported by US Army Medical Research and Development Command. We thank Mrs Flora Richmond, Richard Nawrot and Ybis Sanabria for technical

Micropipetting Cytoplasm from the Mouse Egg

MICROMANIPULATION of living cells presents many intriguing problems because cells are so small and cellular substances are usually viscous. Placing a micropipette into a cell can be accomplished fairly easily by means of a precision micromanipulator, but removing a quantity of cytoplasm from a cell is difficult; to overcome this we have devised a vacuum micropipetting system.

The vacuum micropipetting system consists of a small vacuum pump, a pressure regulator and a plug-valve changer (Fig. 1). Negative pressure can be regulated by a 'Gomco' surgical suction tube, one end having a finger tip control and connexion to the distribution valve, the other end being connected to a vacuum bottle and then to the vacuum pump. Suction is produced by placing the thumb tightly against the finger tip control. Fluctuation of suction pressure within a narrow range can be maintained by the on and off action of the thumb on the finger tip opening of the pressure regulator, so that too fast a flow of cellular materials into the micropipette can be avoided.

The plug-valve changer has two interconnected valves both of which have two outlets. The outlets of one valve are connected by polyethylene tubing to the microinjector and the vacuum pump, while the outlets of the other valve connect with two micropipettes. Thus the function of either pipette can be quickly switched from suction to injection or vice versa.

The vacuum micropipetting system can be used to micromanipulate large and small living cells. In Fig. 2 living newly fertilized mouse eggs of about 70µ in diameter are shown. These were at the pronuclear stage and maintained in a drop of phosphate buffer saline plus bovine plasma albumin (10 mg/ml.) covered with mineral oil

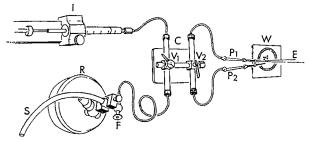

Fig. 1. Diagram of the vacuum micropipetting system. C, Plug-valve changer: V1, outlet valve 1, to microinjector or pressure regulator; V2, outlet valve 2, to micropipette P1 or P2; I, microinjector unit; E, egg-holder pipette; R, pressure regulator; F, finger tip control; S, suction tube to vacuum pump; W, 'Vasellne' well. Details are given in the text.

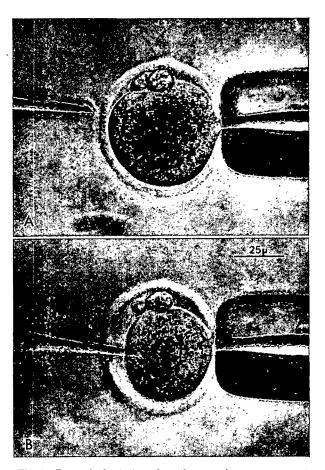

Fig. 2. Removal of cytoplasm from the pronuclear mouse egg. A, Holding of egg before suction; B, holding of same egg during suction. Compare the size of egg vitellus before and after suction.

in a 'Vaseline' well on a microscope slide. Using a Leitz micromanipulator, the egg was held by an "egg holder" which is a fire-polished blunt tipped pipette for holding the egg1, and a microsuctioning pipette with an oblique tip was operated from the opposite side as shown in Fig. 2. Both the egg holder and the suction pipette were maintained in position by a Leitz micromanipulator1.

Suction of the newly fertilized denuded egg can be started when the vacuum pump pressure reaches 125-250 mm of mercury, and the flow of cytoplasmic materials from the egg into the micropipette can be controlled at 505-635 mm of mercury. Negative pressure of 710 mm of mercury can be produced at the tip of the micropipette, but the danger of cells being destroyed is increased.

A pipette with an orifice about 3µ in diameter was used

because: (a) a high negative pressure may be required if too narrow; (b) particulate matter in the egg may block the pipette; and (c) the vitellar substance of the newly fertilized egg of the mouse is very viscous. Fig. 2 illustrates the removal of cytoplasm from the pronuclear mouse egg. Before suction was applied (A) the volume of the egg was estimated to be about 175,820 μ^{3} and the volume of its vitellus about 96,970 μ³. After suction had been applied (B), the size of the egg vitellus decreased, and was calculated to be about 54,365 μ^3 . Nearly half of the cytoplasm was removed from this egg after which the egg was still intact although the vitelline membrane had shrunk.

Reverberi² showed that the fertilized but still undivided egg of Ciona could develop into an embryo even after a large part of its substance had been removed (see also ref. 3). The quantity of cytoplasm removed from a mouse egg may determine its survival; the shrinkage of the vitellus does not cause death. Our previous work4

has shown that some of the shrunken eggs can survive without adverse effect.

I thank Mr Arthur Lutz for constructing the apparatus and Mrs Joan Florence and Mr D. R. Akers for technical assistance. This work was supported by a US Public Health Service grant.

Melanin in an Insect. Lucilia cuprina (Wied.)

MELANINS, although somewhat ill defined, are dark pigments which occur in animals and plants and they are usually bound to protein. Thomson¹ in a review has pointed out that there are no satisfactory histochemical tests for the identification of melanin. Alkali solubility and reversible reduction merely indicate acidic and quinonoid properties-properties common to many different types of pigments. Mammalian and cephalopodan melanins in particular have been extensively studied and some have been isolated and examined chemically. Melanins are formed by the action of a phenolase on a phenolic substrate, but their structure is not known. Those derived from tyrosine, however, are considered to be built up from indolyl units. Nicolaus et al.2 classified melanins as "indole" or "catechol" types, depending on the degradation products formed on alkali fusion and permanganate oxidation. All melanins so far examined from animal sources are of the indole type, as are the melanins prepared by the oxidation of tyrosine and dopa.

In insects, except for one investigation, identification of melanin has relied on inadequate histochemical tests. Sometimes a search has been made for an accompanying phenolase system, but this is usually of little value because of the phenolase activated process of sclerotization which occurs in insects. Nevertheless, sclerotization and blackening (said to be melanin) have been shown to be independent processes in a few insects (for a review, see Hackman4).

I have a laboratory strain of the blowfly Lucilia cuprina (Wied.) in culture which is homozygous for three recessive mutants carrying yellow eyes, rusty body and a black puparium (the puparium of the normal wild strain is brown). Electron microscopy shows a layer of fine black granules at the inner surface of the epicuticle of the puparium. When empty puparia, from which pupal cuticles, other residues and lipids have been removed, are hydrolysed (6 normal hydrochloric acid) thin insoluble membranes remain which are "ghosts" of the original puparia. In the normal wild strain these membranes are colourless, but in the mutant they are an intense black and thicker. When radioactive tyrosine⁵ was injected into fully grown last instar larvae of the mutant, 79 per cent of the radioactivity was recovered from the puparia and 49 per cent of this was in the black membrane remaining after hydrolysis. With the normal wild strain these percentages were 59 and 16, respectively.

The black pigment was extracted (10 per cent aqueous sodium hydroxide) from the insoluble membranes remaining after acidic hydrolysis of puparia of the mutant and recovered by acidifying the extract and yielded 4.6 per cent on weight of puparia taken. The pigment was again subjected to acidic hydrolysis (6 normal hydrochloric acid) for 24 h. In alkaline solution the pigment showed only general absorption in the ultraviolet and visible regions of the spectrum. The pigment was subjected to alkali fusion² and 5,6-dihydroxyindole and 5,6-dihydroxyindole-2-carboxylic acid were identified among the degradation products. Permanganate oxidation6 of the pigment gave pyrrole-2,3,5-tricarboxylic acid as the principal product together with smaller amounts of pyrrole-2,3-dicarboxylic acid and pyrrole-2,3,4,5-tetracarboxylic acid. degradation products are the same as those obtained by Nicolaus and his collaborators^{2,3} from invertebrate melanins (from squid, cuttlefish and octopus inks and from Drosophila melanogaster tumours and Tropinota glabra elytra) and from melanin prepared by oxidation of dopa.

The black pigment in the puparia of the L. cuprina mutant has the physical properties of a melanin and gives degradation products characteristic of melanins of animal origin. This pigment is therefore classified as an indole melanin. Experiments with radioactive tyrosine show it to be formed from tyrosine, which is confirmed by the nature of the degradation products.

Retraction of the Claim that Host Pregnancy affects Pupal Production by the Tsetse Fly

DURING the first two seasons of an investigation into the effect of host pregnancy on female Glossina austeni we claimed that the performance of the flies fed on pregnant goats was significantly better than that of those fed on non-pregnant goats¹⁻³. We must now retract this claim. The combined results for season 2 are given in Table 1, followed by the figures for the first experiment in season 3 in which there was a complete reversal.

Before this investigation began, attempts had been made to test goats for individual variation in attractiveness to fertilized female tsetse, but they failed as a result of concealment of the blood meal by the larva. After checking that the blood picture was normal for the three pregnant goats used in experiment I, we devised a test for the suitability of the host using unfed 2 day old male flies as the test organism. The proportion of such flies which have fed after application for 15 min is referred to as the "host suitability index"; indices were obtained for all goats. There is no evidence that certain goats are basically unattractive, but a few become exceedingly unsuitable because of skin thickening caused by excessive feeding by the flies or by susceptibility to tsetse saliva. Of forty goats tested, four had very low indices. By chance two of these four were in the team of three pregnant goats used in experiment 1; furthermore, all four had been included in the control herds used in seasons 1 and 2, where their presence would have lowered the control values and given rise to apparently better results from the pregnant goats.

Recently two teams of goats with equally high suitability indices were used. The performance of female tsetse flies was remarkably similar when fed on a team of non-pregnant female goats or on a team of castrated male goats (experiment 2A). Using the same goats, the experiment was repeated when the females were pregnant; again, fly performance was similar with the two types of host (experiment 2B). It should be noted that the superiority of these results over those of season 2 resulted from the introduction of a new type of cage2.

The error in the interpretation of our earlier results is extremely unfortunate. On the other hand, by culling any unsuitable animals, excellent yields of pupae can be obtained without having to use pregnant goats which are only seasonally available.

Algebraic Model of the **Lactation Curve in Cattle**

Many factors may influence the total milk yield of a single lactation, but the general shape of the curve, defined by the locus of weekly yield, remains substantially unchanged. Economically, the configuration of the curve is important, for the animal which produces milk at a moderate level steadily throughout her lactation is to be preferred to one which produces a great deal of milk at her peak but little thereafter (see Cersovsky¹ for a review of the literature).

Some attention has been paid to the problem and many workers, chiefly in Europe, have noted changes in the shape of the curve as a result of season of calving2, age3 and fertility4, although the phenomenon appears to remain relatively unaffected by changes in management. British Milk Marketing Board⁵ has presented diagrams showing the effect of season of calving and parity on average lactation curves, and Makela^{6,7} has studied in detail the position and duration of peak yield, and has pointed out its importance to the milk yield of the lactation as a whole.

Little new has in fact emerged since Johanssen⁸ reviewed the subject in 1961, when he described Gaines formula $y = ae^{-Kt}$ (y is the yield in week t, e is the base of natural

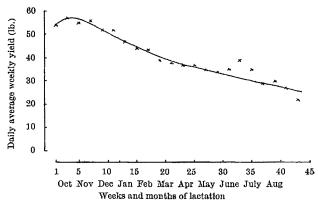

Fig. 1. Regression curve $y = 56.62 \ n^{0.03996} \exp(-0.00942 \ n)$ fitted to a single Friesian lactation.

logarithms, a and K are constants) which, however, does not give a very good fit. More recently, Nelder9 described an inverse polynomial which might furnish a rather better description, but at the same time our own studies have developed along slightly different lines.

The curve of lactation increases rapidly from calving to peak a few weeks later, followed by a more or less gradual decline until the animal goes dry in about 10 months. This is essentially a gamma-type curve, and may be expressed generally by the function

$$y_n = a \ n^b \exp(-cn) \tag{1}$$

where y_n is the average daily yield in the nth week and a, b and c are constants.

The total yield is then

$$y = \frac{a}{c^{b+1}} \vdash (b+1) \tag{2}$$

and yield to week t is given by

$$y_t = a \int_0^t t^b \exp(-ct) dt$$
 (3)

which may be evaluated, for example, by using tables of the incomplete gamma function.

Peak yield occurs therefore where n=b/c and is itself $y_{\max} = a(b/c)b e^{-b}.$

Other properties of the model may be deduced immediately.

The exponent, b, must be less than unity, otherwise we are faced with an ever increasing weekly yield. (b+1), is therefore close to unity, and total yield

$$y \leqslant \frac{a}{c^{b+1}}$$
 (from equation 2)

Hence $c^{b+1} < 1.0$, and so c < 1.0.

But the constant a is a general scaling factor associated with the average daily yield at the start of the lacta-Hence, for tion, because $y_n = a$ when $n^b \exp(-cn) = 1$. lactations starting at the same level, total yield, y, is a function of $c^{-(b+1)}$, which is therefore a measure of "persistency" or the extent to which peak yield is maintained. Putting $S = c^{-(b+1)}$, the relationship between persistency, total yield and level of production is given by

$$\ln(y) = \ln(a) + \ln(S) + \ln(\lceil (b+1))$$

For given a or S therefore variations in y depend almost entirely on variations in S or a, respectively.

The constants may be determined uniquely for any lactation by least squares methods. Equation (1) converts

$$\ln(y_n) = \ln(a) + b \ln(n) - cn \tag{4}$$

a straightforward linear regression model.

Evaluation of a single Friesian lactation chosen at random gave the following values, calculated from the 24 h production of one day in each week for the first 44 weeks of lactation: a = 56.62; b = 0.03996; c = 0.00942; from which $y_{\text{max}} = 57.6$ lb./day, $n_{\text{max}} = 4.25$ weeks.

The observed yield over 305 days was 12,215 lb., which

compares with 12,726 lb. calculated from equation (3), and the persistency factor $c^{-(b+1)}$ is 128.0. The curve is plotted with its expectation in Fig. 1.

If the errors of estimation are normally and independently distributed, a test of significance may be applied to the regression function (4) as in Table 1.

Table 1. REGRESSION ANALYSIS: LOG DAILY YIELD SINGLE LACTATION CURVE Source of variation df. Mean square Lactation curve Residual 0·170200* 0·001315 3 40 * P < 0.001.

The function accounts for 89.7 per cent of total variation in log daily yield, and the standard error of estimate is ± 0.036 , equivalent to ± 8.6 per cent of the expected daily yield. Hence 95 per cent of all errors of estimation will be less than 18.0 per cent of the expected yield.

The configuration of the curve may therefore be defined by three parameters which lend themselves to easy manipulation. If, however, the solution is to have any practical value, it must be possible to discriminate between economically distinguishable groupings and for this a random sample of 524 Friesian heifer lactations classified by sire and herd was taken from the National Milk Records register of calvings during the autumn and winter of 1960-61. Milk yield was recorded on one and the same day (p.m./a.m.) in each week of lactation, and curves were fitted individually.

The sample means of parameters are given in Table 2. Over all lactations, the combined standard error of estimate was ± 0.070 , equivalent to ± 17.5 per cent of expected yield, with 95 per cent limits of ± 38.4 per cent.

Table 2. PARAMETER MEANS

	J.	Tean .

c	_	0.0306	±0.00098	±0.0219
2000				

The standard error and standard deviation given for the constant a are

The hierarchical analysis of variance is given in Table 3 together with the analysis of ln(S) = -(b+1) ln(c), the persistency factor.

Table 3. ANALYSIS OF VARIANCE

		Mean square						
Source of variation	df.	ln(a)	b	$(\times 10^{c7})$	ln(S)			
Between bulls	178	0.0440*	0.0845†	1,388†	0.1345			
Between herds within bulls	199	0.0144	0.0404	829*	0.1599			
Within herds	145	0.0232	0.0348	486	0.1014			
* $P < 0.01$; † $P < 0.00$	01.							

It is evidently possible in this sample to distinguish between progeny groups in respect of the three parameters and between herds in respect of c, but differences in persistency are not sufficiently marked as other workers have also found using other measures.

In Table 4 the principal characteristics of lactation are given for all bull progeny groups of ten or more daughters, and these are plotted in Fig. 2. The relationship between S and a is well demonstrated in Table 4, for example, by bulls 393 and 431. For these two animals the scaling

889	23	29.05	0.2314	0.0311	10,295	7.4	36.6	72	4.2766

factor, a, is almost identical but bull 393 with higher S has the higher yield.

The effect of age, season, disease or breed on the shape of the curve cannot be determined with these data, because all the animals were Friesian autumn-calving heifers, and no other information was recorded. There is, however, some evidence that the shape of the curve is modified particularly by season of calving, in that, superimposed on the basic curve, there is a seasonal fluctuation reflecting the May peak and winter trough noted else-

Effect of Oestradiol and Testosterone on the Sexual Receptivity and Attractiveness of the Female **Rhesus Monkey**

THE ovarian hormones of the female rhesus monkey considerably influence sexual behaviour both in free-living groups¹ and in experimental situations in the laboratory^{2,3}. There are at least two properties in the female which are concerned in her interaction with the male: first, her sexual attractiveness, and second, her sexual receptivitythe willingness of the female to engage in copulation. These two components have now been found to respond differently to alterations in the female's hormonal state.

Experiments were carried out in the laboratory on oppositely sexed pairs of adult rhesus monkeys (Macaca mulatta). The males were intact; the females bilaterally ovariectomized. A series of quantitative observations were made on each pair from behind a one-way mirror after transferring the female to the male's home cage (size $50 \text{ in.} \times 30 \text{ in.} \times 35 \text{ in.}$) for periods of 30 min. All animals were housed singly between observations. Each female was paired successively on the same day, and in the same order, with two males; each series consisted of ten observation periods. Data from different series were compared by analysis of variance and t tests. This report is confined to experiments in which the female was untreated, or receiving either 50 µg/day of oestradiol benzoate or 1 mg/day of testosterone propionate by subcutaneous injection.

The male rhesus monkey copulates by making a series of mounts, each accompanied by intromission and a number of pelvic thrusts, before ejaculating. One way of expressing the level of a male's sexual activity is by means of the "sexual performance index", which is the product of the mean rate at which successive mounts occur and the mean number of thrusts delivered at each mount. This index is correlated with the time the male

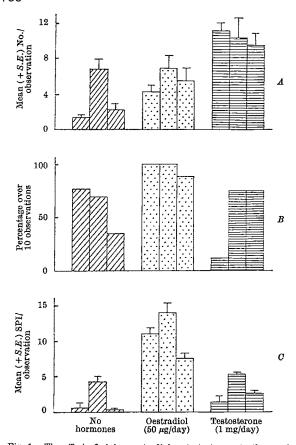

Fig. 1. The effect of giving oestradiol or testosterone to the ovariectomized rhesus monkey on her behaviour with the male. Values given are: means/observation period (A and C) and percentages over a series of ten observation periods (B). Oestradiol increased the female's attractiveness to the male (B) and thus stimulated his sexual activity (C). Testosterone increased the females' presenting behaviour (A), but her attractiveness and hence the male's sexual activity remained low. Examples are shown from three pairs of animals; see text for further details.

takes to ejaculate4, although this relationship is not at issue in this communication. The effect of giving oestradiol to the females of twenty pairs, made up from three males and ten females, was to increase the male's mounting activity (sexual performance index) and number of ejaculations (significantly, fifteen pairs). Females invite the male to mount by "presenting" in a number of ways, but there was no consistent change in the number of times they did so while receiving oestrogen. The mounting activity of the males was stimulated as much in pairs in which the presentations of the female decreased or were unchanged by oestrogen (twelve pairs) as in those in which an increase occurred (seven pairs). The proportion of presentations accepted by the male before ejaculation -that is, resulting in his attempting to mount—was higher when the females were treated with oestrogen (fourteen pairs), and a greater proportion of the male's attempts to mount occurred without being preceded by a recognizable presentation by the female. The females a recognizable presentation by the female. accepted the male's attempts to mount with equal frequency whether they were treated with oestrogen or not.

These results suggest that the administration of oestrogen to the ovariectomized female increases her sexual attractiveness to the male, but that this does not depend on changes in her "presenting" behaviour. If there is any effect on her receptivity, it is much much less than the effect on her attractiveness—a finding in contrast to that on many sub-primate females. The administration of progesterone to a female treated with oestrogen results in a behaviour pattern resembling that with the ovariectomized, untreated female³.

Testosterone was given to the females of eight pairs (three males and four females) and a very different pattern of behaviour resulted. The mean number of presentations offered to the male by the females increased to levels much higher than those in either untreated or oestrogen-treated females (six pairs). But there was only minimal stimulation of the male's sexual activity, and the proportion of the female's presentations accepted by the males remained similar to that in untreated females. Females accepted the male's attempts to mount equally while receiving this dose of testosterone as with oestradiol, and there was no increase in aggression between the animals. Fig. 1 shows data from three of these pairs.

These results indicate that testosterone stimulates the receptivity of the females but has little effect on their attractiveness to the male. The vaginal smears from these animals remained uncornified, although their sexual skins were reddened. This and the data on the effect of oestradiol support the earlier proposition derived from other experiments that intravaginal mechanisms which are sensitive to oestrogen are concerned in the transmission to the male of the state of sexual attractiveness of the female, and indicate that these mechanisms are not stimulated by testosterone. The effect of testosterone on the behaviour of the female monkey has an obvious parallel to clinical reports that androgen, rather than oestrogen, has been found to increase the libido of some women to whom it was administered8,9.

It seems that the sexual receptivity and attractiveness of the female rhesus monkey are affected differentially by oestradiol and testosterone, although further experiments are necessary to decide whether the behavioural role of oestrogen can be attributed principally to an action on the female genitalia, whereas androgen has its effect principally on the central nervous system.

This work was supported by a grant from the Ford Foundation to Sir Solly Zuckerman. We thank him and Professor P. L. Broadhurst for interest and advice.

Antagonism between Cytokinins and Germination Inhibitors

The inhibition of lettuce seed germination by several naturally occurring growth inhibitors is reversed by kinetin in red light. Kinetin in red light also breaks the dormancy in Xanthium seed, presumably by counteracting the inhibitor present in the seed^{2,3}. A similar antagonism between kinetin and coumarin is shown in the germination of Brassica seed⁴. Actinomycin D inhibits the release from dormancy which is induced by kinetin in Xanthium seed2, which suggests that DNA-dependent RNA synthesis is involved in the dormancy release. There is, however, no evidence as yet to suggest whether the endogenous inhibitors act at the same or at different sites. evidence suggests an interplay of cytokinins, growth inhibitors, phytochrome and perhaps other factors in the control of seed germination and dormancy. This communication reports on the interactions in the germination of lettuce seed between zeatin^{5,6} (a naturally occurring cytokinin) and dormin^{7,8} (abscisin II), kinetin and dormin, zeatin and coumarin, and kinetin and coumarin.

Table 1. Effect of Red (R) and far red (FR) light on cytokinin (Kinetin or Zeatin) reversal of dormin inhibition of 'grand rapids' Lettuce seed germination (per cent)

Treatment	Water	Dormin	Dormin + kinetin	Dormin + zeatin
Dark	26	4	8	7
Light	100	6	42	55
R	98	7	35	49
R– FR	20	0	5	7
R– FR – R	98	2	32	40

10 min exposures at 20° C. Germination recorded after 3 days.

Lettuce seeds (Lactuca sativa, var. 'Grand Rapids', 1965 harvest) were germinated in 5 cm Petri plates lined with two disks of filter paper soaked in 2 ml. of test solution. Each experiment had three replicates of fifty seeds each. Emergence of the radicle from the seed coat was taken as the criterion of seed germination. Red light of approximately 800 $\mu W/cm^2$ was obtained by two 15 W, white cool fluorescent tubes covered with two layers of Dupont red 'Cellophane'. Far red light of approximately 800 $\mu W/cm^2$ from a 200 W incandescent bulb was filtered through a running water bath 2.54 cm thick and a Corning Filter No. 2600. Seeds were imbibed for 8 h in dark before exposure to red light. Where both red and far red light treatments were given, one followed the other immediately. Seeds were returned to darkness after light treatments, but in other experiments they were exposed to continuous light of 10 ft.-candles from a white cool fluorescent source.

The antagonism between zeatin and dormin and between kinetin and dormin is shown in Fig. 1. It is clear that dormin is a powerful inhibitor of lettuce seed germination at 25 mg/l. and 50 mg/l. Zeatin and kinetin at 50 mg/l. relieve this inhibition to a great extent. Zeatin and kinetin cause nearly complete reversal of inhibition by 25 mg/l. dormin in 96 h. These results strongly suggest that kinetin and zeatin act in a similar manner, although kinetin appears to be less effective in reversing the dormin inhibition of germination. This is consistent with other reports of the comparative effectiveness of these

Antagonism between kinetin and coumarin in lettuce seed germination has been reported earlier, and a critical examination shows that this antagonism is best brought out at 20° C rather than at lower temperatures. This may be due to the fact that while coumarin is less inhibitory to germination at low temperatures¹⁰, kinetin has little effect on germination between 20° and 25° C. Fig. 2 shows an interaction between zeatin and coumarin and between kinetin and coumarin in their effect on lettuce seed

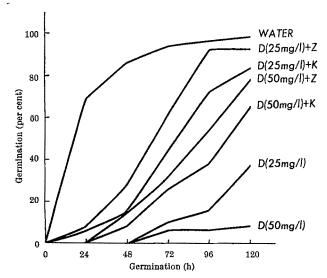

Fig. 1. Interaction between dormin (D) and zeatin (Z) and dormin and kinetin (K) in the germination of Grand Rapids' lettuce seed in continuous light at 20° C. Concentration of zeatin and kinetin: 50 mg/l.

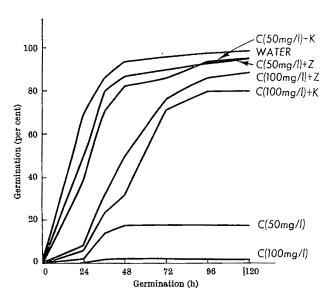

Fig. 2. Interaction between coumarin (C) and zeatin (Z) and coumarin and kinetin (K) in the germination of 'Grand Rapids' lettuce seed in continuous light at 25° C. Concentration of zeatin and kinetin: 50 mg/l.

germination at 25° C. Coumarin is nearly completely inhibitory at 100 mg/l., but this effect is nearly completely reversed by 50 mg/l. zeatin or kinetin. As before (see Fig. 1), zeatin is the more active of the two cytokinins.

An experiment was designed to test whether dormin blocks the red, far red photoreaction and whether this is prevented by cytokinin as shown earlier1. The results in Table 1 show that dormin in fact blocks the photoreversible system and that this is prevented by cytokinins, zeatin and kinetin.

The results reported here, together with other evidence1,2,4, strongly suggest that there is an interplay between the phytochrome system, natural inhibitors and cytokinins which function so as to regulate germination and growth. The mode of action of cytokinins and germination inhibitors is not known. Cytokinins have been shown to induce RNA synthesis 11 as well as to form part of certain transfer RNAs12. More recent work of Chrispeels and Varner13 shows that dormin inhibits the synthesis of gibberellin-induced hydrolases in barley aleurone layers in a manner similar to 6-methylpurine and 8-azaguanine, which suggests that cytokinins and biogenous inhibitors may participate in the regulation of nucleic acid metabolism during seed germination.

I am indebted to Dr Carlos O. Miller, Indiana University, and Dr D. Yeo, Woodstock Agricultural Research Center, for zeatin and dormin, respectively. This work was supported in part by the American Seed Research Foundation.

Response to Photoperiod of Reported Long-day and Intermediate Varieties of Rice

Although Oryza sativa L. is generally considered to be a short-day plant, a delay in flowering by short-day treatment has been reported1-7. Varieties with such a response would have a potential use in studies of physiology and breeding, and would be most interesting ecologically. The data reported on such varieties do not present a clear picture of their reaction, however, and are insufficient to warrant their classification as intermediate, much less long-day, types. To clarify this point, we have carried out detailed tests on several varieties of rice previously reported to be long-day or intermediate. BPI-76', a variety known to be sensitive to photoperiod, was included as a control.

The plants were grown in the greenhouse during the day and transferred to different photoperiods in the evening. Table 1 shows the response of the varieties to photoperiod. All showed responses similar to short-day varieties. None could be regarded as a long-day or intermediate plant.

Table 1. NUMBER OF DAYS FROM SOWING TO FLOWERING OF THIRTEEN VARIETIES OF RICE GROWN AT DIFFERENT PHOTOPERIODS

	Photoperiod (h)					
Variety	8	10	12	13	14	16
'T-3 W356'	88	82	90	98	127	137
'B 76'	76	69	72	79	86	91
'Baok'	136	126	122	125	147	163
'GEB 24'	73	63	90	*	+	+
'CH-10'	78	76	78	78	80	85
'T.21'	91	77	82	88	103	98
T.136'	72	66	69	76	88	92
'Heenati 8963'	81	75	77	77	91	112
'Heenati 8976'	83	73	86	112	165	Ť
'Heenati 8965'	67	51	63	77	90	125

'Karang Serang Sel.'	147	139	123	129	132	153
'BPI-76' (sensitive)	64	65	100	145	Ť	t

* Panicle formation but no emergence after 200 days of growth.

† No panicle initiation after 200 days of growth.

The seeds of 'T-3 W356', 'B 76', 'Baok', 'GEB 24', 'GH-10', 'T.21' and 'T.136' were obtained from the Central Rice Research Institute, Cuttack, India.

The conclusion of previous workers that these varieties were long-day plants, or that short-day treatment delayed flowering, was probably reached because only two photoperiods were tested, one of which was natural day length. For example, if 'Baok' is compared at photoperiods of 8 and 12 h, the 8 h treatment delays flowering by 14 days which leads to the conclusion that it is a long-day plant. The extra photoperiods of 10, 13, 14 and 16 h used in our tests, however, show definitely that it is a quantitative short-day plant. The delay in flowering with an 8 h photoperiod, which is sub-optimum, is a common phenomenon with the short-day rice varieties8,8. Other factors such as temperature may have greatly modified the response of these varieties in previous tests. Varieties like 'BPI-76', 'GEB 24' and 'Heenati 8976' are qualitative, whereas the other varieties are quantitative, short-day

More than a hundred varieties have been critically tested at the International Rice Research Institute and not one, so far, has shown a long-day response.

Relationships among Functional Properties of Californian Grassland

Ecologists have become increasingly interested in general properties of communities and the relationships among species diversity, biomass, productivity, dominance and stability. Both verbal¹ and mathematical² models have been proposed to relate these properties. These models are important as initial generalizations in a developing predictive theory of ecology. The available data, however, are largely from planktonic systems and these data are contradictory. For example, Margalef³ has concluded from his extensive studies of marine systems that productivity and dominance are inversely related to stability and diversity. Increasing species diversity in the community leads to decreased dominance and productivity but increased stability. Patten4, however, has concluded that "high productive capacity is associated with high diversity" in summer plankton communities of Virginia's York River. Studies of grasslands on California's San Francisco peninsula, reported here, provide the first rigorous development of the relationships among diversity, dominance, productivity and stability of terrestrial communities. This report extends Margalef's general model to terrestrial systems and provides strong support for it

as a valid description of general properties of communities. From January 1 to July 1, 1966, standing crop was harvested in three 0.5 m² rectangular quadrats arranged linearly perpendicular to the slope and randomly placed at monthly intervals on north-east, north-west, southeast and south-west slopes on sandstone and serpentine soil types on Stanford University's Jasper Ridge Biological Experimental Area. The area studied had been free of grazing and fire for more than 5 years previously, undoubtedly long enough for the vegetation to come to equilibrium considering the rapidity with which this vegetation type responds after disturbance. Oven dried material from monthly samplings provided data on biomass and productivity of the grasslands during the principal productive period. During May, the month of peak standing crop, diversity data were collected by canopy interceptions along two 5 m transects on each sampling site with sampling points fixed at intervals according to fifty random numbers between 0 and 500 One transect was perpendicular to the slope and one was parallel to the slope. Dominance was assessed as a "dominance index" equal to the percentage of the total standing crop contributed by the two most important species. I am concerned here with the general properties of the grasslands as a model system and a more detailed treatment of their ecology will appear

Dominance in the grasslands was related to diversity according to Y=138-6.6~X, where Y is the percentage of the peak standing crop contributed by the two most

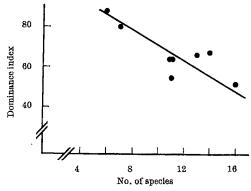

Fig. 1. Relationship between dominance (as percentage of total standing crop contributed by two most important species) and species diversity of grasslands on Stanford University's Jasper Ridge.

important species and X is the number of species recorded from 100 random points on the two transects (Fig. 1). The inverse correlation between these two properties is very significant (r = -0.842; 0.01 > P > 0.01). These data indicate that the tendency for biomass to become concentrated in a limited number of species decreases as the community becomes floristically richer.

The productivity of the Jasper Ridge grasslands was directly related to dominance according to Y = -0.79 +0.0188 X, where Y is productivity in g/m²/day and X is dominance as previously defined (Fig. 2). Productivity and dominance were significantly correlated (r = 0.852; 0.01 > P > 0.001), indicating that the efficiency of the grasslands as an energy-trapping system increases with increasing concentration of biomass in a limited number of species. The least diverse site was more than 2.5 times productive than the most diverse site.

Stability of communities can be estimated from the turnover time, the ratio of biomass to productivity. The greater the biomass in relation to productivity, the less dependent the community is on conditions favourable to productivity to maintain a relatively stable biomass. An elegant theoretical justification of this argument has been developed by Leigh2. In the California grasslands, stability declined with productivity according to Y = 3.95 -3.52~X, where Y is turnover time in years and X is productivity as previously defined (Fig. 3). The signoductivity nificant inverse correlation (r = -0.829; 0.02 > P)0.01) suggests that the community becomes increasingly susceptible to alteration in functional properties through environmental oscillation as productivity increases. rather severe price in stability seems to be paid for the increased productivity generated by greater dominance.

Although general, non-quantitative discussion of the ideas developed here is widespread among ecologists 10, this is the first time data from terrestrial systems have been rigorously related to the concepts in Margalef's model. I conclude from these data that dominance is directly related to productivity and inversely related to diversity and stability and infer the following general properties of communities: (a) diversity is principally a mechanism which generates community stability; (b) dominance is principally a mechanism which generates community productivity; and (c) increasing the number of species in a stand, rather than enhancing efficiency through more efficient exploitation of site resources, decreases efficiency, perhaps through competition. The similarity between the California grasslands and Margalef's planktonic communities emphasizes the general application of Margalef's conclusions to ecological systems and suggests that these conclusions represent extremely significant ecological generalizations.

The data presented here were collected during the tenure of a US Public Health Service postdoctoral traineeship

CYTOLOGY

Mitogenetic Radiation

Between 1920 and 1935 a great deal was published on the subject of mitogenetic radiation—a radiation usually considered to be ultraviolet, which is emitted by dividing cells and which stimulates other cells to divide. studies were originated by Gurwitsch1 and are still carried on in the Soviet Union, but almost ceased in Britain and the United States in the 1930s after much careful but negative work²⁻⁴. Nobody there was able to stimulate cell division with weak ultraviolet light or to detect radiation from rapidly dividing cells with photoelectric or biological detectors.

The sensitivity of photon counters has increased more than 200 times since the 1930s and modern equipment has been claimed to detect radiation from yeast and tissue cultures⁵⁻¹⁰. This communication reports an attempt to check these measurements.

According to a communication from Gurwitsch's laboratory quoted by Troitskiis, two drops of 6 per cent oxalic acid added to 3 ml. of 0.2 per cent potassium permanganate emit radiation of intensity similar to mitogenetic radiation. We have constructed a photon counter which readily measures light in the range 2000-6000 Å from this reaction.

The photon counter was equipped with an EMI 6255SAphotomultiplier which has a large 4 cm diameter photocathode. An air gap (1 mm) and a 3 cm silica light guide separate the photocathode from a silica cuvette of 25 ml. capacity, all of 4 cm diameter and coated externally with magnesium oxide which increases the light reaching the photocathode about tenfold. If the cell or light-guide

touch the photocathode, spurious pulses are observed when liquids enter or leave the cell

Previous workers⁵⁻¹⁰ have specialized in ultra-low background counts which are increased slightly when the detector is exposed to dividing cells. This procedure is open to the objection that very low count rates are easily falsified by external interference of a temporary and unpredictable nature. We have preferred to accept the higher background counts from a large photocathode which can view a much larger volume of cell culture.

Suspensions of yeast or bacteria in their rapidly dividing logarithmic phase of growth (as shown by opacity measurements) were introduced into the cell by a syringe through a long, black plastic tube. The yeast and bacteria were suspended in a nutrient medium of soy trypticase broth which emitted detectable phosphorescence for up to 5 min after it entered the cell. After this no light could be detected from any of the yeast or bacterial suspensions listed in Table 1, although the light from the reference solution of Troitskii⁵ was easily measured with the same equipment.

We conclude that any radiation from these growing cells must be less than one-fifth of that from the reference solution quoted as a source of light comparable with mitogenetic radiation.

We thank the late Mr F. M. Hilder of the Christchurch Public Hospital for preparing yeast and bacterial cultures and the New Zealand Universities Grants Committee for an equipment grant.

Genetic Loads affecting Longevity in Natural Populations of Drosophila pseudoobscura

GENETIC loads consist of deleterious genes or gene complexes mostly recessive and concealed in the heterozygous state. The heterozygous individuals found in natural populations are usually superior in fitness to inbred progenies, which are made in part homozygous. This superiority is manifested in two ways: (a) the heterozygous combinations have a higher average in most components of the Darwinian fitness; (b) their phenotypic variability tends to be lower, because of the better buffering ability against environmental fluctuations1.

The components of genetic loads which reduce the viability of their carriers have been extensively studied, but considerably less information is available about the behaviour of other fitness components, particularly longevity. Many workers, however, have repeatedly observed the depressing effect of inbreeding on the mean life span of Drosophila2-5. Vetukhiv⁶ discovered a generalized heterosis for what concerns longevity, in crossing the strains of *D. pseudoobscura* from different localities. Spiess and Schuellein, on the other hand, working with different homo- and hetero-karyotypes of D. persimilis, found an average superiority of the heterokaryotypes in the rate of development, egg to adult survival and in fecundity, but not in longevity. This is why we decided to carry out a simultaneous analysis of the longevities of females, homozygous and heterozygous for the second chromosomes from natural populations of *Drosophila* pseudoobscura. An analysis of two other components of fitness-viability and fecundity-was also performed on the same material.

The samples of *D. pseudoobscura* were collected in November 1966 near Tucson (Arizona) by Dr W. Heed and at Borrego Valley (California) by Mr D. Richmond. To obtain the homo- and hetero-zygotes for wild second chromosomes, we used a standard technique⁸⁻¹⁰. longevity of the females was observed in sixty-seven homozygotes and in thirty-four heterozygous combinations, using three to five replications. Each replicate culture contained a group of ten flies which were kept in 9.5×2.5 cm vials with a synthetic medium and a constant amount of yeast11. The flies were placed in the vials after a mild etherization less than 24 h after emergence, and kept in an incubator at 25° C, with a humidity of 65-70 per cent. The numbers of dead flies were recorded on alternate days, and the medium was changed every fourth day. Fecundity and viability were studied in the same sixty-seven homozygotes and thirty-four heterozygous combinations, as described by Marinkovic¹⁰.

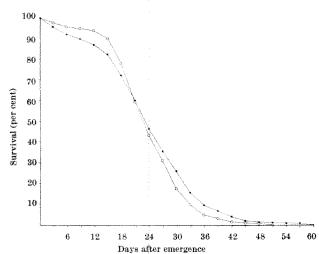

The mean longevities, viabilities and fecundities of the homozygotes and the random heterozygous combinations of wild second chromosomes are presented in Table 1. As was found earlier⁸⁻¹⁰, the viability and the fecundity of the homozygotes are significantly lower compared with the heterozygous controls (P < 0.001). The mean lon-

Table 1. Mean longevity (days), viability (per cent of wild type flies in the cultures) and fedundity (number of eggs laid in six days) of the females homozygous and heterozygous for wild second CHROMOSOMES

	Homozy $(N=0)$	gotes 87)	Heterozygotes $(N=34)$		
	x SE	S ²	x SE		
Longevity Viability	23.55 ± 0.77 28.88 ± 0.69	39·31 31·21	23.62 ± 0.63 34.12 ± 0.56		
Fecundity	151·3 ±7·3	3553.4	204·4 ± 8·0	2169-7	

gevities, however, are the same: the average longevity of the homozygotes is 23.6 ± 0.8 days and among the heterozygotes 23.6 ± 0.6 days. The variances in all three analysed characters are greater among the homozygotes (the variance ratios for the longevity and viability are significant at less than 0.02 and for the fecundity at P < 0.1, using a two-tailed test).

The correlation coefficients were calculated between the longevity and viability or fecundity of the homo- and hetero-zygotes. Among the homozygotes, a significant positive correlation was found between longevity and viability (r = 0.320; P < 0.02). Longevity and fecundity were also positively correlated, but the value is not significant (r = 0.183). Among the heterozygotes a high correlation was obtained between longevity and fecundity (r = 0.474) and a lack of correlation between the longevity and viability was found (r = 0.012). The calculated coefficients of correlation between longevity and viability or fecundity suggest a physiological relationship between them. A larger number of chromosomes, especially of heterozygotes, however, must be studied to ascertain the existence or non-existence of correlation of these characters.

-

and hetero-

Fig. 1 contains the survival curves of the flies which are homozygous (N = 2,206 individuals) and heterozygous (N = 1,184) for wild second chromosomes. The length of life among the homozygotes ranges from 1 to 60 days, while among the heterozygotes it ranges from I to 51 days. A probit test shows that a sigmoid function can be applied to both curves. Although the two curves look very much alike, the variance of the survival of the homozygous flies is greater than that of their heterozygous relatives ($F_{60^{\circ}48}=1.62$; P<0.1), giving a slightly higher level of probability than when the variances among the chromosomes and their combinations were compared.

These results suggest that (a) there is no difference in mean longevity between the homo- and hetero-zygotes, and (b) there is a statistical difference in the variances of these two groups.

Maynard-Smith12 pointed out a special importance of genes with sex limited effects on the longevity of D. subobscura, and Moriwaki and Tobari13 found that the Y chromosome is important in determining the longevity of the males in *D. melanogaster*. The lack of the difference in our experiment between the mean longevities of the homo- and hetero-zygotes for wild second chromosomes provides further information about the unequal role of factors located on different chromosomes in the determination of this character

Another property of the heterozygotes, namely, their smaller phenotypic variability, appears clearly in our results in all three analysed characters. It should be emphasized, however, that this variability is at the same time genotypic and environmental. The absence of difference in average longevity, associated with a significant difference in the variances of the homo- and hetero-zygotes, gives some indication of independence between these two parameters. On this basis, we would not agree with Rasmuson¹⁴ that an increase in environmental variance among the homozygotes is produced We would rather agree by their lower adaptedness. with Donald15 that a decrease in a component of the fitness and reduction of the buffering ability of the homozygotes are both concomitant consequences of inbreeding, and in the case of the factors studied, which are determining longevity, they seem to be independent.

Transformation of Primary Rat Embryo Cells by a Weakly Oncogenic Adenovirus—Type 3

Although human adenovirus types 3 (ref. 1), 7 (ref. 2), 12 (ref. 3), 18 (ref. 4), 14, 16, 21 (unpublished work of M. Pina and M. Green) and 31 (ref. 5) have been shown to be oncogenic in hamsters and, in some cases, mice and rats as well, in vitro transformation has been reported only for "highly oncogenic" types 12 (refs. 6-9) and 18 (unpublished results of Rafajko and Huebner). primary rat embryo cells and a selective medium containing 0.1 mmolar calcium, a quantitative transformation system has been reported for adenovirus type 12 (ref. 9). It seemed that a similar system for the "weakly oncogenie" adenoviruses would be useful for quantitative studies of transformation by these two groups of adenoviruses, and this communication reports the transformation of rat cells by adenovirus type 3.

Primary cultures of cells derived from decapitated, near-term, inbred, Fisher rat embryos were planted in culture tubes with an inoculum of 105 cells/ml. in Hagle's basal medium¹⁰ supplemented with 10 per cent foetal bovine serum and 0.2 mmolar non-essential amino-acids. The cultures were fed on the third day and ineculated when confluent, usually on the fifth day after seeding. Adenovirus type 3, strain 15-520 (ref. 1) (titre 10° ID_{se}/ml. as determined by titration in primary human embryonic kidney (HEK) cultures), was inoculated into drained cultures, 0.1 ml. of virus stock in each tube. The purity of the adenovirus 3 pool was tested by breakthrough neutralization tests against type specific adenovirus type 3 rabbit antiserum in rhesus monkey kidney cultures¹ These tests were observed for 21 days, at which time 0.2 ml. of the culture fluid was blind passed into each of three HEK cultures. No cytopathic effect occurred in the HEK cultures during a 3 week observation period, indicating that the seed virus had been neutralized by adenovirus type 3 antiserum. Further, by means of complement fixation tests stock virus used in these experiments was found to be free of adenovirus associated viruses (AAV) types 1-4 (ref. 14). The cultures were incubated at 37° C for a 2 h adsorption period and the tubes were rotated at 15-20 min intervals. Low calcium medium (1 ml.)15,16 (Eagle's minimum essential medium without calcium, supplemented with 0.1 mmolar calcium chloride, 5 per cent dialysed calf serum, 2 per cent foetal bovine serum and 0.2 mmolar non-essential amino-acids) was added to each tube. The cultures were re-fed at 2-3 day intervals and were maintained in a stationary position in atmosphere containing 5 per cent carbon dioxide in air. Cultures were observed for at least 60 days.

No cytopathogenic effects were observed in the inocuted cultures. Thirty-five days after inoculation, there lated cultures. appeared, against a fibroblastic background, morphologically altered areas consisting of small epithelioid cells forming distinct domed foci (Fig. 1) similar to those previously described in primary rat embryo cultures transformed by adenovirus type 12 (ref. 9). Although the number of tubes with foci continued to increase up to 50 days after inoculation, the number of foci in each individual tube remained quite constant. At the end of 60 days some tubes contained no foci, some contained a single focus, sometimes 6-8 mm in diameter and some tubes contained two or three foci. At this low frequency of foci in a tube, any foci caused by re-seeding could not have altered the rate of transformation significantly. In each of two experiments, twenty-seven tubes/dilution were inoculated with virus doses ranging from 106 to 108 HEK ID₅₀/0·1 ml. Based on the original virus inoculum, the rate of transformation was linear, with approximately

P 29	32	< 4	< 4	< 4

1-2 transformation events occurring for each 108 infectious virus doses (Table 1). Based on the number of rat cells in each tube at the time of inoculation, approximately 0.0003 per cent of the cells were transformed by the inoculum containing the highest virus dose. Previously, it has been reported that approximately 106 infectious doses of adenovirus type 12 were required for one transformation event in rat cells and that 0.01 per cent of the cells were transformed9.

Some of the cultures bearing transformed foci were subdivided and six cell lines were derived from the two experiments. During the first ten to fifteen passage levels these lines contained low but significant complement fixation titres¹⁷ of tumour (T) antigen when tested against a pool of serum obtained from animals bearing transplanted tumours originally induced with adenovirus type This serum pool was used because it was difficult to obtain high titre sera from hamsters bearing adenovirus type 3 tumours1; adenovirus types 3 and 7 tumour antigens are known to cross react1. At a higher passage level, one of the cell lines transformed by type 3, No. 8426, produced tumour antigen with high complement fixation activity (Table 2). The results of a complement fixation test shown in Table 2 indicated that the rat cells had been transformed specifically by an adenovirus of the type 3-7 sub-group, because there was no evidence of T antigen induced by adenovirus type 12 or SV40. There was no serological evidence of infectious adenovirus in the transformed cells. The specificity of the transformation was substantiated further by the following tests. At the twenty-second passage level, the cells of line 8426 were stained directly with a hamster tumour (adenovirus type 7 induced) serum which had been conjugated with fluorescein isothiocyanate. Almost all of the cells contained the nuclear "fleck" antigen which has been described in adenovirus tumour or transformed cells6. Using SV40 hamster tumour sera, however, indirect fluorescent antibody studies were negative. Thus it was unlikely that an adenovirus 3-SV40 hybrid virus was responsible for the cell transformation because virtually all cells transformed by this hybrid contained the SV40 tumour antigen in the nucleus as determined by fluorescent antibody tests18.

Fujinaga and Green have reported that cell lines, derived from hamster tumours induced by adenovirus type 3, yield messenger mRNA which hybridized with the DNA of adenovirus types 3 and 7, but not with that of adenovirus types 12 or 18 (ref. 19). One of the rat embryo cell lines transformed by adenovirus type 3 was studied by these investigators and was also found to contain mRNA which hybridized with DNA from adenovirus type 3 but not with DNA from adenovirus type 12 (personal communication from M. Green and K. Fujinaga).

Not tested.
 4-8 units of serum was used in each test.
 Reciprocal of complement fixation titre.

To substantiate the results of complement fixation which suggested that cell line 8426 was free of infectious virus, a 20 per cent frozen and thawed extract of each cell line was inoculated and sub-passaged in ten primary human embryonic kidney cultures. Both sets of culture were observed for 21 days without evidence of infectious

Between the fifteenth and eighteenth passage levels 106 cells of each of three transformed cell lines were inoculated subcutaneously into newborn Fisher rats, and sixteen out of fifty-eight developed tumours 50-60 days after inoculation. Histological examination showed that these tumours contained uniform, small, "undifferentiated sarcoma" cells which were typical of those described in adenovirus induced tumours. A cell line was derived from one of the tumours and, at passage 3, a 20 per cent extract had an adenovirus 3 tumour antigen complement fixation titre of 1:4. Sera from animals bearing tumours 3-7 cm in diameter did not contain demonstrable levels of T antibody. When these tumours were transplanted into weanling rats, however, T antibody was found which, diluted 1:40, reacted with adenovirus 3 or adenovirus 7 tumour antigen. There were no tumours in eleven newborn rats inoculated subcutaneously with the slower growing control rat embryo cells which were at the sixth passage level.

We thank Dr K. Schell for seed adenovirus type 3, and

Dr H. J. Igel for pathology reports.

Fixation of Ejaculated Spermatozoa for Electron Microscopy

EJACULATED spermatozoa cannot be preserved satisfactorily by conventional fixation procedures for electron microscopy. Osmium tetroxide (OsO4) fixation of crude ejaculate consistently produces a variety of artefacts such as separation of the plasma membrane from the

acrosome, widening of nuclear vacuoles, erosion of the acrosome, and swelling of mitochondria1-3. These alterations could be the consequence of the rapid destruction of the fixative by the proteins of the seminal plasma. Similar results are obtained whenever the semen is washed either in salt solutions3,4 or in other media5-7 before osmium tetroxide fixation. In these cases, the structural alterations of the sperm are probably caused by osmotie imbalances. Fixation with glutaraldehyde is also unsuecessful in that it is associated with the typical artefacts of this fixative (our unpublished work).

Previous fixation experiments with a buffered pierie acid-formaldehyde (PAF) solution had shown that this fixative penetrates faster than conventional electron microscopy fixatives, and it is affected only a little by tissue fluids and plasma proteins8. Spermatozoa were very well preserved when the PAF fixative was tested on

human ejaculates.

The fixative, a modification of Bouin fluid, is prepared as follows: 20 g of para-formaldehyde is added to 150 ml. of a double-filtered, saturated aqueous solution of pierie acid. Dissociation of the para-formaldehyde into formaldehyde in the strong pieric acid solution is obtained by heat (about 60° C) and on alkalinization of the mixture with drops of a 2.52 per cent sodium hydroxide in water. Thus a clear solution is obtained, which is filtered in a cylinder, allowed to cool, and then made up to 1,000 ml. with a phosphate buffer used by Karlsson and Schultz for perfusion fixation of the central nervous system. The buffer is prepared by dissolving 3.31 g of NaH2PO4.H2O and 33.77 g of Na₂HPO₄.7H₂O in 1 l. of water. The PAF fixative has an osmolarity of 900 mOsm and a pH of 7.3. The fixative can be prepared in large quantities because it is very stable and withstands exposure to light at room temperature for 12 months without deteriorating.

The first two drops of the ejaculate are collected directly into 20 ml. of PAF at room temperature. The seminal plasma coagulates immediately into clumps of different sizes. These consist mostly of proteinaceous components of the seminal plasma precipitated in a granular form, and very few spermatozoa. These clumps, including those at the limit of visibility, are removed to obtain a nearly pure cellular suspension which is spun for 10 min at 1,000 r.p.m. The supernatant is discarded (fixation time is about 25 min), and the pellet of highly concentrated spermatozoa (Fig. 2d) is washed for 15 min in several changes of phosphate buffer. It is then post-fixed for 15 min in 10 ml. of 1 per cent osmium tetroxide¹⁰, and rapidly dehydrated. The pellet is finally reduced into small fragments and embedded in 'Epon 812'.

With this fixation procedure the spermatozoa show intact plasma membranes (Fig. 1 and Fig. 2a), well preserved acrosomes (Fig. 1b), nuclear vacuoles of a

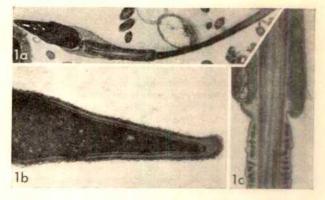

Fig. 1. (a) Longitudinal section of a spermatozoon in the human semen (×4,500). (b) Anterior portion of a sperm head. Note the integrity of acrosome and plasma membrane, and the close relationship between these two structures. The nuclear vacuoles are uniformly small (×16,500). (c) Transitional area between middle and principal piece of sperm flagellum (×22,000). All are stained with lead hydroxide.

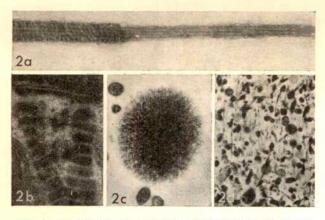

Fig. 2. (a) Principal and end pieces of the flagellum of a human ejaculated spermatozoon. The plasma membrane is continuous throughout and closely adherent to the underlying structures (\times 16,000), (b) Cross-section through the proximal centriole (\times 52,500), (c) Semian plasma components precipitated in a crystalline form (\times 8,750). (d) Light microscopic picture showing the high concentration of spermatozoa in the pellet. (Section about $\ln c$ in thickness, \times 675.) (a, b and c stained with lead hydroxide and d with toluidine blue.)

consistently small diameter (Fig. 1b), well preserved flagella (Fig. 1a and c, and 2a and b), and mitochondria of uniform density (Fig. 1a and c). Areas of separation between plasma membrane and acrosome are not observed (Fig. 1b). There are numerous crystals of a varying size among the spermatozoa (Fig. 2c). presence of these crystals, which obviously consist of inorganic components of the seminal plasma precipitated by the fixative, makes the blocks difficult to section. This inconvenience is eliminated by using very soft 'Epon' mixtures (7 parts of 'Epon A' and 3 parts of 'Epon B').

Vital Staining of Insect Eggs by Incorporation of Trypan Blue

MORPHOGENETIC movements which occur during the early stages of animal embryogenesis are difficult to study unless some kind of marking technique is used. In vertebrates vital staining of small cell patches1 or application of charcoal powder² has permitted the construction of maps showing extensive morphogenetic movements during early embryogenesis. Similar techniques have proved useful for the study of morphogenesis in other animal phyla. There are, however, no reports on successful intra vitam staining of insect eggs. This may be because the protective covers of most insect eggs do not permit dyes to enter locally, while eggs deprived of their covers cease to develop. Morphogenetic movements taking place during the plasmodial stages³ of insect Morphogenetic movements embryogenesis therefore had to be reconstructed from a series of fixed material4-6 or were analysed by using local defects as markers7,8 and by time lapse studies7,9,10. Defect marking more than other techniques involves the danger of misinterpretation. Time lapse studies and investigations on fixed material share the disadvantage that only a limited range of structures located in the egg plasmodium can be traced satisfactorily, for example, nuclei or special inclusions of the cytoplasm; furthermore, work with fixed material is technically difficult and cinematography fails to reveal movements within bulky eggs sufficiently clearly. Renewed attempts to overcome these handicaps have produced a technique which, although far from being as versatile as vital staining in amphibians, serves to reveal the type and extent of movements within the whole egg plasmodium of the house cricket (Acheta domesticus L.) during germ band formation and anatrepsis.

The technique is based on the observation 11 that trypan blue injected into females of Panorpa is incorporated into growing oocytes in a way similar to the incorporation of proteins from haemolymph into yolk bodies. A short pulse of trypan blue offered to growing oocytes of different sizes should therefore lead to incorporation of the dye into different concentric yolk layers. In the house cricket, this result is obtained by injecting 0.03 ml. of 0.7 per cent trypan blue dissolved in insect Ringer solution into virgin These are mated the following day and are allowed to oviposit 1 day later, when a certain percentage of the eggs will be stained in different layers of the yolk system (Fig. 1). The females survive and can be used for

another injection some days later.

In most eggs studied the stain was confined to the yolk bodies and remained so for at least the first half of embryogenesis; however, in very rare instances the trypan blue appeared to be attached to material which soon was taken up by the cytoplasmic islands of certain vitellophages. The percentage of stained eggs failing to develop varies somewhat but does not notably exceed the percentage observed in eggs of untreated females. The remaining eggs develop quite normally although trypan blue is highly teratogenic in vertebrates12; the development may merely proceed more slowly. Owing to the rather uniform distribution of the stain within the coloured layer the technique at present does not permit the construction of fate maps showing the positions of prospective organs. The marking of different egg layers, however, is very instructive so far as translocation of materials within the egg plasmodium is concerned. Eggs stained superficially corroborate on the whole the results of earlier studies¹³. Streaming movements of surface material collect many preblastoderm nuclei at two regions

Eggs of cricket with trypan blue incorporated into different yers of the yolk system. Unstained control at the right. Fig. 1. Eggs of cricket states layers of the yolk system.

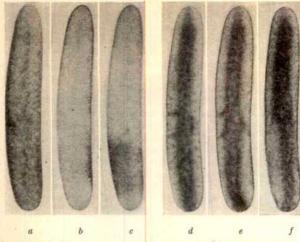

Fig. 2. Distribution of stained material in three corresponding stages of a superficially stained egg (a-e) and of an egg stained around its central core (d-f) as seen from the left-hand side.

situated dorsolaterally on each side of the posterior half of the egg. From there they are moved ventrally to form the germ anlage while more material is added from the anterior surface of the egg. Photographs taken at different stages of development reflect these movements by the varying distribution of stained material (Fig. 2a-c). Staining of deeper egg layers reveals that the movements shaping the superficial germ anlage are not limited to the surface. The surface streams are matched by extensive shifting of material deep inside the egg plasmodium. When the surface material moves dorsolaterally, the central mass of the posterior egg half is found displaced ventrally (Fig. 2b and e), while postero-ventral movements on the surface are compensated by dorsal and forward movements of central material (Fig. 2c and f). The whole yolk system is involved also in the initial stages of the movement of germ anlage around the posterior egg pole (anatrepsis)¹⁴. During this movement the plasmodial system is agitated by a series of slow and predominantly internal movements best described as internal peristalsis, and thereby becomes divided into separate yolk cells.

Incorporation of trypan blue into growing oocytes has been achieved in a number of other insect species as well. In these, however, differential staining of egg layers may not be equally good because it is influenced by varying parameters such as rate of protein incorporation into the ovary, speed of oocyte growth, and uptake of the stain by other organs of the mother. Nevertheless, the technique after suitable modification should prove useful for further research in insect embryology.

Effect of Adenosine Diphosphate on Adhesiveness of Platelets in vitro and in vivo

Adenosine diphosphate (ADP) is known to cause reversible aggregation of human and animal platelets in vitro1-4. Hellem et al.5 used a column of glass beads6 to determine an increase, within certain limits, in the adhesiveness of platelets in response to ADP. Born and Cross and Chins have also shown that intravascular injection of ADP produces a rapid and transient decrease in the number of circulating platelets, which is probably caused by the adhesion of platelets to the endothelium and the aggregation of platelets leading to intravascular trapping?. and Stehbens, have used ear chambers to demonstrate the intravascular aggregation of platelets in rabbits caused by intravenous infusion of ADP

We have added ADP (Sigma Chemical Co.) to the citrated whole blood of healthy subjects in vitro to study the changes in platelet adhesiveness with the glass filter method10. As Fig. 1 shows, the adhesiveness began to increase 10 min after the addition of ADP, and had reached its maximum and returned to the initial value within 50 min. The decrease in the platelet count of filtered blood5,10 might thus be caused by the capture in the filter of the mass of aggregated platelets as well as the adhesion of platelets to the surface of the filter glass. Our experiments also confirm that the increase in the adhesiveness of platelets induced by ADP is reversible.

We have also studied the influence of intravascularly injected ADP on circulating platelets in rabbits. Fig. 2 shows the number of circulating platelets and the fluctuation of adhesive and non-adhesive platelets, measured by the glass filter method, after the injection of 10 mg of ADP in physiological saline into the marginal vein of the ear lobe of four healthy rabbits. After the intravenous injection of ADP, the circulating platelets started to decrease, reaching a minimum 20 min later, and then returned towards the initial concentration except in one rabbit. Together with the marked decrease in the circulating platelets there was a pronounced fall of the adhesive platelets, although non-adhesive platelets showed scarcely any change. No such decreases were seen when physiological saline alone was injected. Thus the decrease reported7,8 in circulating platelets in response to the injection of ADP was confirmed. The decrease in adhesive platelets which was seen at the same time can be explained by the intravascular reversible adhesion or aggregation of platelets in response to ADP which causes them to become trapped in the endothelium. On the other hand, the absence of changes in non-adhesive platelets is difficult

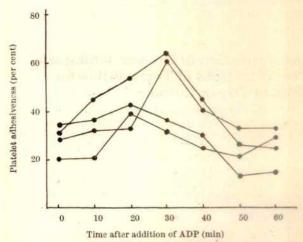

Fig. 1. Changes in adhesiveness of platelets after addition of ADP as a solution in physiological saline, in a final concentration of 0-1 μ g/ml., of citrated whole blood collected from four healthy donors. ADP added at zero time.

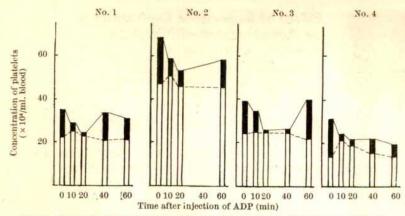

Fig. 2. Changes in circulating platelet count and the number of adhesive and non-adhesive platelets after intravenous injection of 10 mg of ADP into four rabbits, ADP injected at zero time. Columns represent circulating platelet count: _____, adhesive platelets; ______, non-adhesive platelets.

to explain, except by the difference in the dose of ADP used. The effect on the increase in the platelet adhesiveness of the concentration of the ADP added has certain limitations in vitro11. The mechanism of adhesion of platelets to a glass surface or to each other through the action of ADP is not yet clear, however, and a different reaction mechanism seems to be involved between platelet adhesion and aggregation. Further investigation is also necessary before it can be decided whether there are two different kinds of platelets—one which reacts with ADP and one which does not.

Determination of Growth Inhibitory Concentrations of Tetracycline for Bone in Organ Culture

Long bones of premature children given tetracycline in therapeutically high dosages have shown up to 40 per cent growth inhibition during 2-4 weeks of treatment1. This effect was reversible, and approximately 2 weeks after the last administration of tetracycline the growth rate returned to normal. It is well known that large doses of tetracycline depress overall growth of chick embryos and mice2, but in other studies when therapeutic doses of tetracycline were given to rats and humans, growth inhibition was not observed^{3,4}. It seemed probable that growth inhibition was dose dependent and that perhaps growth inhibiting concentrations of tetracycline could be reached in premature human infants, and so we decided to determine whether tetracycline would inhibit

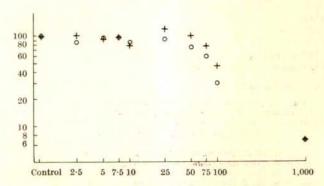

long bone growth in an organ culture system and, if so, at what concentration of tetracycline in the medium the inhibition The method developed by occurred. Proffit and Ackerman⁵, which evaluates growth of bone by measuring uptake of tritiated thymidine and of 14C proline from the culture medium, was used. Separate experiments indicated that, although there was some uptake of calcium-45 into bone spicules, there was no calcification of cartilage in this system. culture method is similar to that used by Saxén⁶⁻⁸, who observed effects of tetracycline on calcification of immature bone in vitro but did not describe an effect on growth.

Five day old rats were killed and four bones from each forepaw (first, second and third metacarpal and third phalanx) were placed on small sections of 'Millipore'

filter in a plasma-thrombin clot. The bones were then placed in culture tubes containing standard 199 medium, supplemented with penicillin-streptomycin and 10 per cent horse serum. Labelled proline and thymidine were added to monitor the synthesis of structural protein and DNA, respectively. Tetracycline was included in and DNA, respectively. varying concentrations from 0 to 1,000 µg/ml. The pH of the medium was found to be independent of the amount of tetracycline except at a concentration of 1,000 µg/ml. when a lowering of 0-15 U was observed. Bones were cultured in a roller drum apparatus at 37° C. After 6 days in culture, isotope uptake was evaluated by liquid scintillation counting of the residue after the dried bones had been burned. In addition, other bones were cultured in control and tetracycline containing media for histological examination.

Fig. 1 shows graphically the uptake of tritiated thymi-dine and ¹⁴C-proline. The decrease in uptake of tritiated thymidine is statistically significant (P < 0.01) at 50 The effects of tetracycline on the uptake of ug/ml. ¹⁴C-proline are significant at 75 μ g/ml. (P < 0.005).

Ultraviolet microscopic examination of bones cultured in medium containing tetracycline revealed the golden yellow fluorescence characteristic of tetracycline in the cartilage lacunae, in the fibrous capsule to a lesser extent, and in the calcified parts of the bones. Fig. 2 shows a control and an experimental section of the cartilage. Brightly fluorescing areas in the cartilage lacunae can be clearly seen. These fluorescent areas are probably not the nuclei, they are more likely to be in the cytoplasm of the cell. Loose binding of tetracycline to cytoplasmic elements has been noted with several other tissues9-11, but the particular affinity for maturing cartilage cells in this system is interesting.

Concentration of tetracycline in medium (µg/ml.)

Fig. 1. Uptake of tritiated thymidine and ¹⁴C-proline as a function of tetracycline concentration in the culture medium (control considered as 100).

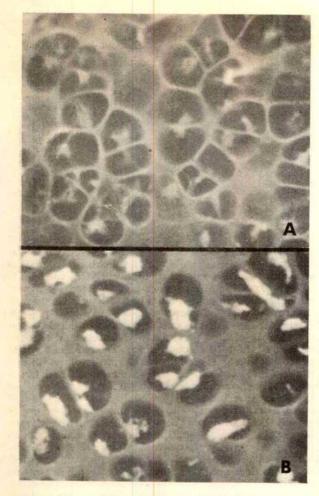

Fig. 2. Fluorescence photomicrographs of proliferating cartilage from rat metacarpal. A, Control, cultured in medium without tetracycline; B, experimental, cultured with tetracycline in medium (40 μg/ml.), Fluorescent areas, representing tetracycline, can be seen in the cartilage lacunae.

Finland¹² reported that in adult human males given therapeutic doses of tetracycline, the amount of drug circulating in the serum was about 4 µg/ml. From our data, which indicate that about 50 µg/ml. of tetracycline in the medium depresses long bone growth, it does seem possible that serum concentrations in premature infants given tetracycline could become large enough to depress long bone growth. The mechanism of direct incorporation of tetracycline into cartilage probably explains the inhibitory effect, for growth of long bones in vivo and of the metacarpals used in these in vitro experiments depends largely on proliferation of cartilage cells. It is probable that the tetracycline is much less tightly bound to cartilage than to calcifying bone, and that growth of the bones for a short time in a medium not containing tetracycline would remove the drug from the cartilage cells.

MICROBIOLOGY

Influence of Pulmonary Dust Load on the Development of Experimental Infection by Mycobacterium kansasii

For a long time1 it has been known that the experimental infection of guinea-pigs could be aggravated by exposure to silica particles. Many surveys have tried to specify the interactions: "dust-infection" into lungs. We have determined the pathogenic role of Mycobacterium kansasii in guinea-pigs exposed to the inhalation of mineral dust particles²⁻⁷ and have established the following facts. (a) Dust particles aggravate experimental infection by Mycobacterium kansasii, and dusting is liable to make pathogenic a certain dose of bacteria which, without dust, would not induce lesions. (b) There is increased severity of the pulmonary lesions when there is dusting before, but not after the inoculation of an infecting dose of about 5 x 105 micro-organisms. (c) The previously established absence 8-11 of increased virulence of the strains after passage and extensive multiplication in dusted animals is confirmed and so is (d) the exacerbation and precociousness of tuberculin-allergy after the double

aggression of dust and mycobacterial infection.

We have assessed the importance of the quantity of dust particles contained in the lungs12,13 and have used a precise qualitative and quantitative means of dusting. Mycobacterium kansasii, the part of which in human pulmonary pathology is recognized, was given intravenously to avoid the over-traumatizing intratracheal route. Three series of experiments were performed with guinea-pigs weighing approximately 500 g each, and with three different kinds of dust: group 1, 98 per cent coal and 2 per cent quartz (final pulmonary concentration in quartz was 5 per cent); groups 2 and 3, 85 per cent coal and 15 per cent quartz (final concentration in quartz was 30 per cent). Coal was estimated by the method of King and Gilchrist*, and quartz by King's method¹4. Dusting was effected in automatically regulated cages, during 3 and 6 days, and 2, 3, 6 and 8 weeks, in order to obtain increasing amounts of dust particles in the lungs. The members of each experimental group were injected intravenously, on the same day, with Mycobacterium kansasii, variety luciflavum strain WR. Group 1 received 800,000 bacilli, group 2 770,000 bacilli and group 3 650,000 bacilli. Groups 1 and 3 were killed after 6 weeks and group 2 after 12 weeks.

The weight of the guinea-pigs was checked, weekly systematic pulmonary radiography was carried out before infection and on days 30 and 45 after inoculation of bacteria, and, on the same days, tuberculin allergy was investigated. At the end of the experiments, the lesion index was recorded for each animal according to a preestablished scale; the right lungs were removed for bacteriological examination, and the viable mycobacterial units were counted, while the left lungs and mediastinal lymph nodes were kept for histopathological study. The extent of the specific lesions, with respect to the total pulmonary parenchyma, was estimated in the left lungs by cutting off and weighing the projections of the histological lesions on 'Kodatrace' paper.

The changes in weight, radiological opacities and tuberculin reactions are of little significance, and the intensity of the lesions in each experimental group was estimated from the number of bacilli cultivated from the

right lungs, the anatomical lesion index and the histological lesion index.

There is a statistical correlation between the duration of dusting and the amount of dust detained in the lungs on the one hand, and the intensity of the tuberculous lesions on the other hand. In each group of guinea-pigs the coniotic content of the lungs increased in proportion with the duration of dusting (Table 1). There is a very close correlation between these two parameters. nodular lesions enumerated on the surface of the pulmonary lobes were all the more numerous and voluminous as dusting increased and the dust content became large. The statistical correlation between these two parameters is remarkably significant.

The extent of the tuberculous lesions, assessed by graphical analysis of the histological sections, is proportional to the quantity of dust particles inhaled, whatever may be the initial content of quartz particles (2 or 15 per cent) in the mixture of coal and quartz employed. The importance of the final pulmonary concentration in quartz (comparison of groups 1 and 3) has not promoted the spread of the tuberculous lesions, probably because of the protective power of coal with respect to quartz, a

property which we have recently detected 15

The histological aspect of the lesions remained identical after 6 weeks, in all the animals of groups 1 and 3. The lesions consisted of tuberculous nodules frequently with necrotic centres containing dust. In contrast, the cellular reaction area constituting the tuberculous granuloma was rather poor in mineral particles. It was surrounded by a peripheral area devoid of real fibrous capsule, but in which the alveolar septa seemed to be thickened and infiltrated. The alveoli in process of collapse are coated with cuboidal cells and enclose pulmonary macrophages heavily loaded with mineral particles.

After 3 months' infection (group 2), the lesions were more fibrous and less extensive than in the animals killed 1.5 months after mycobacterial inoculation. The absence of fundamental distinctive histological characteristics between the lesions observed in these animals and those exposed to the inhalation of a mixture poorer in quartz seems to be worth recording. The spontaneously regressive characteristics of the tuberculous histological lesions progressively lessened while the amount of pulmonary dust particles increased. The comparison between the bacteriological and anatomo-pathological results shows that, beyond a certain limit in dust load, the tuberculous lesions become spontaneously irreversible (during our periods of observation).

In each of the experiments, the number of the viable mycobacterial units isolated from the right lungs was proportional to the dust content of the lungs. In this respect, the coefficients of statistical correlation are very significant. For the same dusting (a mixture of 85 per cent coal and 15 per cent quartz), extended to periods of 3-20 days, fewer bacilli were isolated from the right lungs after 3 months infection than after 1.5 months. This bacteriological aspect of the regressive characteristics of the tuberculous lesions is no longer observed when the dust content exceeds a certain threshold. Beyond this threshold, tuberculosis was spontaneously irreversible.

These experiments on guinea-pigs infected by Mycobacterium kansasii, after a more or less long inhalation of a mixture of coal and quartz particles in variable proportions, show the existence of a linear relationship between the quantity of dust particles in the lungs and the importance of the tuberculous lesions. The excellent statistical correlation observed between the means of the various criteria (dust content, indexes of anatomical and histological lesions, counting of the viable mycobacteria in the lungs) emphasizes the proportionality between the importance of the dust deposits in the lungs and the aggravation of the infection. For light dustings, involving a moderate charge, the pneumoconio-tuberculous lesions prove spontaneously regressive 3 months after myeobacterial inoculation. Nevertheless, this regressive aspect of the lesions does not appear any more after an important dusting involving a higher dust content. This fact, supported by bacteriological and anatomo-pathological arguments, involves the existence of a threshold in the pulmonary dust content beyond which specific lesions become spontaneously irreversible.

effects of Anti-thymocyte Serum on 17-D Yellow Fever Infection in Adult Mice

Many neurotropic viral infections are accompanied by inflammatory cellular infiltrates of the central nervous system. With some of these viruses, notably lymphocytic choriomeningitis (LCM), the cellular response is believed to be responsible for the morbidity and mortality associated with infection1, and suppression of the lymphocytic response by treatment with anti-thymocyte serum prevents clinical signs of disease2,5. Yellow fever infection caused by the 17-D virus in mice is characterized by a diffuse encephalomyelitis consisting of mononuclear cell infiltration of leptomeninges and perivascular areas, as well as neuronal degeneration and glial proliferation4. We have used rabbit anti-mouse thymocyte (RAMT) serum to prevent cellular responsiveness to 17-D virus, in order to evaluate the role of delayed hypersensitivity in the pathogenesis of experimental yellow fever.

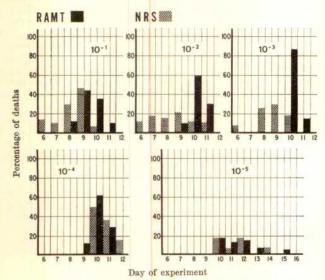

Fig. 1. Comparison of times of death in groups treated with normal rabbit serum (NRS) or rabbit anti-mouse thymocyte (RAMT) serum, at virus dilutions from 10⁻¹ to 10⁻².

Adult ICR mice of both sexes were used in all experiments. RAMT serum was prepared as described by Levey and Medawars, and assayed by its ability to (a) diminish peripheral blood lymphocyte counts by 50 per cent within 4 h, and (b) prevent clinical and histological evidence of lymphocytic choriomeningitis in ICR mice inoculated with LCM virus when 1 week old. All RAMT sera were shown to be free of anti-yellow fever activity by mouse neutralization assay. The virus used was a 20 per cent w/v suspension of suckling mouse brain of 17-D vaccine strain passed three times in adult mice and twice in suckling mice. It contained 104.4 LD 50/0.03 ml. when titrated by intracerebral inoculation of adult ICR mice. A hundred and seventy-two mice were divided into two equal groups, one which received RAMT serum, the other normal rabbit serum (NRS). The sera were intraperitoneally administered in 0.3 ml. volumes at 3 day intervals beginning 1 week before virus inoculation, and ending at the termination of the experiment. The virus was intracerebrally inoculated on day 0 in 0.03 ml. volumes, in dilutions of 10-1-10-6. The animals were observed daily for signs of clinical illness. Animals which died were autopsied, and sections of their organs were examined by light microscopy. Titrations of individual brains from both groups killed on the same day were performed by intracerebral inoculation of adult mice.

At low dilutions of virus (10⁻¹, 10⁻², 10⁻³), mice treated with NRS developed clinical illness 1-2 days earlier than

Fig. 2. Brain section of mouse treated with 10⁻⁴ dilution of 17-D virus and NRS, dying 12 days after infection. Meningeal and perivascular inflammatory infiltrates present. Stained with haematoxylin and eosin (× 525).

their counterparts treated with RAMT serum. As shown in Fig. 1, the times of death at these dilutions were also delayed by treatment with RAMT serum, although only at two dilutions $(10^{-2}, 10^{-3})$ were the differences highly significant $(P < 0.01, \text{ using the } \chi^2 \text{ approximation of the Kolmogorov–Smirnov non-parametric test). At higher dilutions <math>(10^{-4}, 10^{-5})$ no differences in morbidity or mortality were observed between the two groups. Other than the times of onset and death at low dilutions, the clinical features of the illness in both groups were identical. The animals first became hypokinetic, and shortly afterwards they developed progressive and ascending flaccid paralysis, ruffled fur, conjunctivitis and dehydration.

Histological examination revealed marked differences between dying animals of both groups at all dilutions. While animals treated with NRS showed characteristic leptomeningeal and perivascular infiltrates of brains, these findings were nearly absent in animals treated with RAMT serum (Figs. 2 and 3). Neurones in both groups showed moderate degenerative changes with focal decreases in Nissl substance, pyknosis of nuclei and cell liquefaction. Virus titres in brains of animals killed on the same days were equivalent in both groups at all dilutions, despite the differences in histological findings.

These studies suggest that the inflammatory reaction to 17-D virus in adult mice plays a slight but significant potentiating part in the development of morbidity and mortality after virus inoculation at low dilutions. That the antiserum is not acting against either the virus itself or the target cell of the virus is indicated by (a) the absence of 17-D neutralizing activity in RAMT serum and (b) the absence of differences in virus titre between the experimental and control groups. It is also clear, however, that the cellular response is not of primary importance in the pathogenesis of 17-D infection in adult mice, as it is in lymphocytic choriomeningitis virus infection*,3; neither is the cellular response apparently necessary for protection from the effects of the virus, as evidenced by equal LD_{50} titres in both groups. The reasons for the lack of protective effect of RAMT serum at higher virus dilutions are obscure. Perhaps with the smaller virus doses and subsequently longer incubation periods, other host mechanisms, such as humoral antibody formation

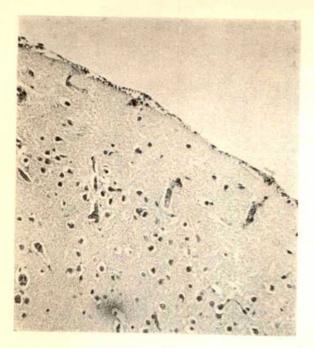

Fig. 3. Brain section of mouse treated with 10⁻⁴ dilution of 17-D virus and RAMT serum, dying 12 days after infection. Inflammatory infiltrate minimal. Stained with haematoxylin and cosin stain (×525).

or reticulo-endothelial activity, are more important defence mechanisms than delayed cellular immunity.

IMMUNOLOGY

Inhibition of Complementary Lysis by Rheumatoid Sera

In suitable conditions, anti-γ-globulin inhibits lysis of sensitized red cells1. Rheumatoid factor is apparently an antibody against γ-globulin, and so it might be expected to do the same. This report describes the results of "inhibition of lysis" titrations on sera from normal subjects and patients with rheumatoid arthritis, and shows that the correlation with sensitized sheep cell agglutination tests and latex fixation tests is high.

Heimer et al.2 have reported that whole rheumatoid sera delay the lysis of sensitized sheep erythrocytes rather more when human heterophil antibody, as opposed to rabbit-produced amboceptor, is used to sensitize the cells. This inhibition of lysis they attributed chiefly to a material designated "inhibitor (Ag-Ab)" which was distinct from rheumatoid factor^{2,3}, although it may be simply the moiety of rheumatoid factor with primary specificity for human-γ-globulin4. The amount of "inhibitor (Ag-Ab)" correlates well with latex fixation titre⁵.

Most of Heimer's work^{2,3,5} is related to the ability of "inhibitor (Ag-Ab)" to inhibit complement fixation by a

specific precipitate (human thyroglobulin and rabbitproduced antibody against it) and is less relevant to the present work, although the mechanism involved may be the same. Schmid and Roitt⁶ have also briefly reported inhibition of complementary lysis using rheumatoid materials and have found good correlation with agglutination tests for rheumatoid factor.

In the present work, the sensitivity of the test for inhibition of lysis was increased in several ways, as follows. Romeyn and Onysko1 have shown that complement (C') and anti-γ-globulin compete for sites on sensitized cells. Furthermore, because the anti-y-globulin delays rather than inhibits lysis entirely, the equilibrium between sensitized cells and anti-y-globulin appears to be a dynamic one in which molecules of anti-y-globulin are released and later re-attach themselves so that gradually the C' can attach and accomplish lysis of most of the cells. Furthermore, any other material in the suspending fluid, notably free \gamma-globulin, can unite with anti-y-globulin and inhibit its attachment to sensitized sites. Thus three things are done to increase the sensitivity of the test: first, the sensitized cells are washed free of other rabbit serum components before adding to the test sera; second, the sera are allowed to react with the sensitized cells for 20 min before C' is added; and third, the final lytic incubation after C' is added is shortened to 20 min. In such tests it is also necessary to ensure that inhibition of lysis is not simply caused by destruction of C' and the method for doing this is described

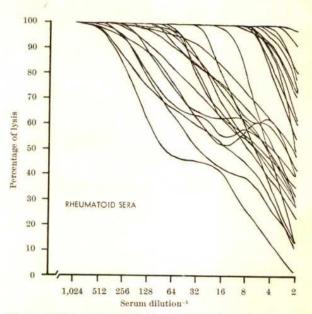

Fig. 1. Inhibition of haemolysis titration curves of sera from twenty-seven rheumatoid arthritis patients.

The technique was essentially that described by Romeyn and Onysko¹ except that group O Rh-negative human cells and amboceptor produced by rabbits against them were used instead of sheep erythrocytes, which would have been lysed by heterophil antibody in the test sera. Briefly, the test involves serially diluting the serum, adding erythrocytes sensitized with $3\,HD_{50}$ amboceptor (washed after sensitization and before use in the test) and incubating for 20 min at 37° C. Guinea-pig C' is then added, $4HD_{50}$, and the mixture incubated for a further 20 min at 37° C. After centrifugation in the cold, the supernatants are read spectrophotometrically against blanks in which untreated red cells are used instead of sensitized cells. Percentage lysis is calculated, using as 100 per cent lysis the reading obtained in a tube in which the serum is replaced by saline.

Any reduction in lysis to less than 100 per cent might be caused by destruction of complement or protective union of rheumatoid factor with the sensitized cells. The test to rule out C' destruction depends on a substantial though not absolute specificity of rheumatoid factor for rabbit as opposed to guinea-pig-γ-globulin. Therefore. to 3.0 ml. of the supernatants are added after reading 1.0 ml. amounts of rabbit erythrocytes sensitized with amboceptor produced by guinea-pigs and then washed. After incubation for 20 min at 37° C and centrifugation, spectrophotometric readings are again made using the same blanks as before. The resultant increase in optical density approaches (but does not quite reach) 100 per cent lysis of the rabbit erythrocytes, indicating no substantial destruction of complement in the original test. This test is carried out after all inhibition of lysis titrations.

It is worth remarking that, when complement fixation tests are performed on rheumatoid sera (for syphilis, for example), the sera are often reported to be anti-complementary. It seems probable from our experience that what is actually occurring in the serum control is not

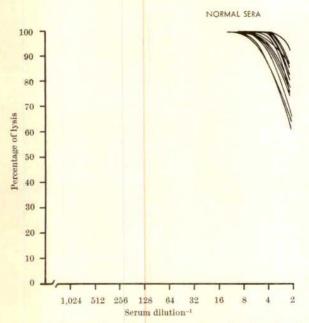

Fig. 2. Inhibition of haemolysis titration curves of sera from twenty normal humans.

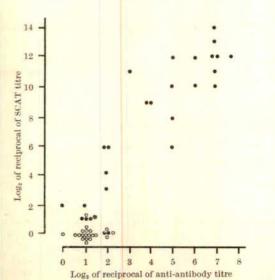

Fig. 3. Scatter diagrams of sensitized sheep cell agglutination titres (SCAT) and inhibition of haemolysis titres on twenty-seven rheumatoid and twenty normal sera. ●, Rheumatoid; ○, normal.

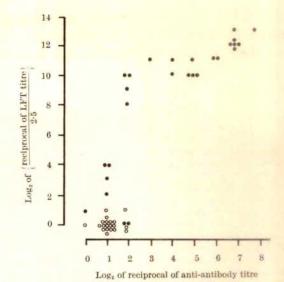

Fig. 4. Scatter diagrams of latex fixation titres (LFT) and inhibition of haemolysis titres on twenty-seven rheumatoid and twenty normal sera. •, Rheumatoid; O, normal.

complement destruction but inhibition of lysis through the protective mechanism operative in the presently reported tests.

Figs. 1 and 2 show the titration curves for twentyseven sera from rheumatoid arthritis patients (ages 25-78 yr, mean 51 yr, 78 per cent female) and twenty sera from normal subjects (ages 23-60 yr, mean 42 yr, 65 per cent female), respectively. It is clear that the rheumatoid sera differ markedly from the normal sera, although there is some inhibition of lysis produced by normal sera at high concentration (1:2 and 1:4).

Sheep cell agglutination titres (SCAT) and latex fixation titres (LFT) were also determined. For comparison with these, the "inhibition of lysis titre" was defined as the least concentration of serum required to produce at least 7.5 per cent inhibition of lysis, using the initial serum concentrations before the addition of cells and complement. Figs. 3 and 4 are scatter diagrams showing the relation of inhibition of lysis titres to SCAT and LFT. Log to a base 2 of the reciprocals of the SCAT titre and of

reciprocal of LFT titre is plotted on these figures (and

was also used in calculating the correlation coefficients). The figures show a high positive correlation between the tests. The correlation coefficient relating inhibition of lysis titre to SCAT was 0.89 (P=0.001), and relating inhibition of lysis titre to LFT was 0-81 (P = 0.001)

Although inhibition of lysis correlates well with SCAT and LFT, in this small series it was not more sensitive or more specific in distinguishing normals from patients.

We thank Dr F. D. Baragar and his staff at the Manitoba Rehabilitation Hospital for the rheumatoid sera and the Medical Research Council of Canada for a grant.

Immunological Cross-reactivity between Plasma Membrane and Endoplasmic Reticulum of Ehrlich Ascites Carcinoma

MICROSOMAL membranes of Ehrlich ascites carcinoma can be separated into membrane classes of high and low density, which on the basis of enzyme, physiochemical and immunological criteria 1-4 are considered to be derived from endoplasmic reticulum and plasma membrane, respectively. Because the membranes from the endoplasmic reticulum lack the antigens involved in the agglutination and/or immune lysis of intact Ehrlich ascites carcinoma by rabbit and horse antisera directed against microsomal membranes of Ehrlich ascites carcinoma^{1,2}, we wished to test, by means of antibody-binding, whether there are not some antigens which the two membrane classes have in common.

Plasma membrane, endoplasmic reticulum and immune horse immunoglobulin were prepared as in earlier work^{1,2}. The immunoglobulin was labelled with 14C-acetic anhydride5 without loss of agglutinating activity from the carcinoma. Antibody absorption by plasma membrane and endoplasmic reticulum was measured by equilibrating stated amounts of membrane and immunoglobulin in 1 ml. of 0·15 molar sodium chloride, 0·005 molar calcium chloride, 0.01 molar tris hydrochloric acid (pH 7.4) for 16 h at 0° C, and then for 0.5 h at 37° C. The samples were then made to 5.0 ml. with the buffer and centrifuged for 45 min at 50,000 r.p.m. and 4° C (Spinco L-2 ultracentrifuge, rotor SW 50). The supernatants were decanted, the tubes fully drained and the pellets resuspended in 5.0 ml. 0.15 molar sodium chloride and 0.005 molar calcium chloride. After another centrifugation at 50,000 r.p.m. and 4° C for 45 min. the supernatants were again decanted, the tubes drained and carefully blotted on the inside and the pellets suspended in 0.5 ml. 0.15 molar sodium chloride. Samples (0.05 ml.) of these suspensions were mixed with 1.0 ml. of hydroxide of hyamine 10x (Packard Instrument Co.) and 10 ml. of Bray's solution and counted to 5 per cent error in a Tricarb liquid scintillation counter. The supernatants and appropriate dilutions of unabsorbed immunoglobulin were counted in the same way. All counts were carried out in duplicate as was each absorption experiment. We used two different membrane preparations and two lots of labelled antibody prepared from the same antiserum. To measure antigens common to endoplasmic reticulum and plasma membrane the immunoglobulin was first absorbed with varying amounts of endoplasmic reticulum as described. The pellets of endoplasmic reticulum were then removed by centrifugation and samples of the supernatants equilibrated with a constant amount of plasma membrane for $16\,\mathrm{h}$ at $0^{\circ}\,\mathrm{C}$ and $30\,\mathrm{min}$ at $37^{\circ}\,\mathrm{C}$. The plasma membrane pellets were then sedimented, washed and counted. Preliminary studies showed negligible absorption of normal horse immunoglobulin and showed that the washing procedure used was adequate to reduce adventitious counts to insignificant levels. Labelled immunoglobulin was used as the internal standard and results are thus expressed as μg of immunoglobulin absorbed by plasma membrane or endoplasmic reticulum.

Absorption tests with plasma membrane show that, below an immunoglobulin: membrane weight ratio of 2, the amount of antibody absorbed is constant (about 0.04 mg/mg). Specific absorption declines with higher proportions of antigen and is about 0.02 mg/mg at a 1:1 With endoplasmic reticulum (Fig. $\bar{1}$, curve a) specific antibody absorption progressively diminishes as the proportion of antigen increases. Maximum antibody binding is attained at an immunoglobulin: endoplasmic reticulum ratio of 0.5. Further increases in the proportion of endoplasmic reticulum do not lead to additional absorption of antibody. When a given amount of antibody (0.7 mg) is first equilibrated with increasing amounts of endoplasmic reticulum (as in Fig. 1a), and, after removal

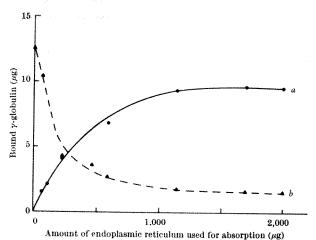

Fig. 1. Antibody-binding by plasma membrane and endoplasmic reticulum. (a) —— Antibody-absorption curve of endoplasmic reticulum. 0-7 mg of immunoglobulin was equilibrated with the amounts of endoplasmic reticulum shown, under the conditions given in the text. (b) A - - - A, Decrease in the antibody bound by 0-5 mg of plasma membrane after prior absorption of the immunoglobulin with increasing amounts of endoplasmic reticulum.

of the endoplasmic reticulum, is absorbed with a constant amount (0.5 mg) of plasma membrane, curve b in Fig. 1 results. This shows a reduction in the amount of antibody bound to plasma membrane from 0.025 mg/mg of membrane in the controls to 0.003-0.004 mg/mg after absorption with excess endoplasmic reticulum.

These results, which show that there are antigenic sites on plasma membrane which are either lacking or inaccessible in endoplasmic reticulum, are consistent with the previous demonstration1,2 of the lack of absorption by endoplasmic reticulum of horse anti-Ehrlich ascites careinoma agglutinating antibody. On the other hand, the data also imply that the two membrane classes, although differing in a number of critical features, have several structural components in common.

Effects of Phytohaemagglutinin on Homograft Rejection

Although phytohaemagglutinin (PHA) has been widely investigated in vitro, relatively little is known about its effects in vivo1. It has been used in humans with aplastic anaemia, who subsequently showed evidence of increased bone marrow activity in some cases2. Gamble3 found that intravenous injection of PHA in mice resulted in increases in the cellularity, the proportion of immature cells, and the weight of the spleen, which were most marked 3 days after administration. Calne et al.4 used combined PHA and azathioprine ('Imuran') therapy in an attempt to prolong the survival times of renal homotransplants in dogs. Intravenous PHA potentiated the immunosuppressive action of azathioprine and was thought to have some immunosuppressive activity when used alone.

Because of the stimulating effect of PHA on lymphocytes in vitro, it is conceivable that there would be a profound effect on the immune system of the organism if adequate concentrations could be attained in vivo. If generalized de-differentiation occurred in the lymphoid system of the organism after administration of PHA, it is possible that the ability to respond to antigenic stimulus would be severely compromised. The work reported here was designed to determine whether PHA in vivo has any effect on the ability of a host to reject a skin homograft.

Mixed male and female closed colony White Swiss and inbred virgin C57BL mice, aged 2-3 months, and weighing between 27 and 44 g, obtained from Roswell Park, Buffalo, New York, were used. PHA was injected in doses of 0.5 ml. into the tail veins of mice with sterile tuberculin syringes and 27 gauge needles and the maximum dose tolerated was determined by injecting increasing amounts of PHA. Most of the animals survived a dose of 0.5 ml., whereas most animals died after injections of 1.0 ml. Phytohaemagglutinin M (General Biochemicals) used in this project is apparently not as toxic to mice as PHA-M (Difco), which has been used extensively by other investigators. Whereas Micklem⁵ found a mortality rate of 50 per cent using 0.4 ml. of PHA (Difco), most of the animals we used survived the standard dose of 0.5 ml. PHA (General Biochemicals). Several of the mice in group 1, however, showed gross hepatic necrosis on autopsy which was apparently similar to that found in 50 per cent of Micklem's animals.

The mice were divided into four groups (Table 1). Group 1 consisted of eight White Swiss male (WSM) and eight White Swiss female (WSF) mice. Four were killed immediately and the remaining twelve animals were given 0.5 ml. of PHA and killed on subsequent days in groups of two, beginning 2 days after injection. Body weights, spleen weights and peripheral white blood cell counts were recorded and spleen smears were made. Group 2 consisted of five WSM and five WSF mice which received 0.5 ml. of PHA and the skin homograft on the same day. Another dose of PHA was given 3 days later. The technique of skin grafting and observation is described in ref. 6. Group 3 consisted of five WSM and five WSF mice which received 0.5 ml. of PHA 3 days before the skin graft, on the day of the graft, and 3 days after it. Group 4 consisted of four animals treated like those in Group 3, except that they were injected with saline rather than PHA.

After necropsy of the animals in Group 1, the spleen was placed on a dry filter paper and immediately weighed

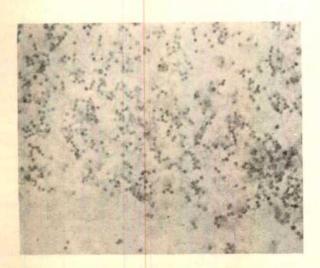

Fig 1. Low power magnification of a control spleen smear.

Fig. 2. Low power magnification of a spleen smear, 4 days after administration of PHA.

on a Mettler analytical balance to the nearest 0.0001 g. The spleen was macerated between two glass slides and the smear stained with Wright's stain.

Peripheral white blood cell counts on the animals in Group 1 revealed counts ranging between 6,100 cells/mm³ and 16,850 cells/mm³. No trend was established during the 6 days after administration of PHA. The peripheral white blood cell count was inconclusive as a criterion of the *in vivo* effect of PHA, perhaps because of many variables in production, release, and sequestration of leucocytes.

Gamble³ found earlier that PHA affected spleen weight and cellularity, and we confirmed this (Table 2). The average spleen weight of the control animals was 0·1144 g, and the average ratio of spleen weight to body weight was 0·00286. The values obtained from the animals which received PHA were moderately elevated with very little overlap into the control group, both in splenic weights and in the ratios of spleen weight to body weight.

Figs. 1-4 illustrate the differences observed in the spleen smears under high and low power magnification. Fig. 1

Table 1. SPLEEN WEIGHTS AND SPLEEN WEIGHT/BODY WEIGHT RATIOS AFTER INTRAVENOUS ADMINISTRATION OF PHA

No significant difference in homograft rejection is apparent between animals treated with PHA and controls treated with saline.

is from a mouse which received no PHA, and Fig. 2 is from a mouse 4 days after intravenous administration of PHA. The absence of small, dark-staining lymphocytes and the presence of larger, more immature cells are quite evident in the second photomicrograph. High power magnifications of normal spleen cells as compared with those stimulated by PHA are shown, respectively, in Figs. 3 and 4.

The twenty-four White Swiss mice bearing skin homografts from C57BL mice all rejected their grafts without any significant deviation from the normal rejection time⁶. Neither the dosage of PHA nor the timing of its administration in relation to application of the skin homograft caused any prolongation or shortening of the rejection time. The length of time that a homograft will remain compatible was previously determined at this laboratory to be 9±1 days7. Rejection times in this project ranged from 8 to 11 days, with only one of the grafts becoming incompatible on day 11 (Table 2).

Intravenous administration of PHA in divided doses of 1.0 to 1.5 ml. failed to alter significantly first-set homograft rejection times. Animals receiving lesser doses of PHA showed evidence of lymphoid mitogenic activity in their spleens. The failure of PHA to render the animals immunologically tolerant may be caused by a variety of factors⁸⁻¹⁰. One possibility is that an inadequate concentration of PHA or an inadequate period of exposure to PHA was attained for its full biological effect to be

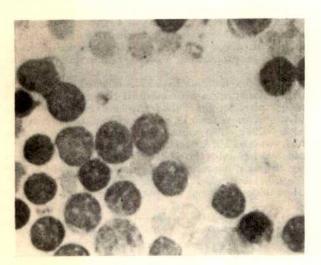

Fig. 3. High power magnification of a control spleen smear.

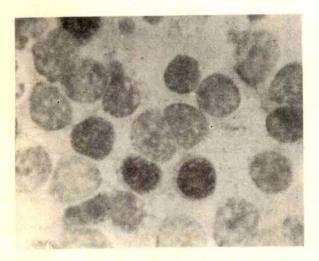

Fig. 4. High power magnification of a spleen smear 4 days after administration of PHA.

exhibited. Toxicity becomes a problem with higher dosesand is usually manifested by sudden death. Because PHA is a relatively crude extract, further biochemical study may, in the future, yield a pure substance of high mitogenic activity and lower toxicity.

In vitro studies reveal that PHA affects 70-95 per cent of the cells in lymphocyte cultures. The percentage of lymphoid cells that are affected in vivo is unknown. Even if PHA concentration was optimal, there might still exist in vivo enough functional, mature lymphocytes to maintain unaltered defences against foreign antigens 11,12.

A less likely possibility is that, in spite of a profound effect on the morphology and kinetics of the lymphocyte, stimulation with PHA may not alter its ability to react with foreign histocompatibility antigens.

GENETICS

Serum Albumin Polymorphism in North American Indians

ALBUMIN variants, migrating anodally to the usual type in starch gel, cellulose acetate and paper electrophoretic systems, have been reported in Algonkian-speaking and neighbouring North American Indian populations1 and in several Indian and non-Indian pedigrees2-5. Variation in the electrophoretic mobility of the Indian and one non-Indian, fast migrating variant has been established1. An additional albumin variant with a slow electrophoretic mobility occurs, with relatively high frequency, in Mexican Indian populations1, and has been observed in a Pima population of the south-western United States (our unpublished work).

We have examined sera from northern Minnesota Indians with varying degrees of Ojibwa-Anglo genetic admixture and a representative sample of Blackfoot Indians from Montana (our unpublished work). sera were diluted 1:7 with 0.15 molar sodium chloride before vertical starch gel electrophoresis was carried out for 8-10 h at 11 V/cm and 4° C. Starch gels, consisting of 15 g per cent hydrolysed starch, were prepared according to Bowman and Bearn⁶. In both populations an albumin variant with identical electrophoretic mobility on vertical starch and polyacrylamide gels has been encountered migrating anodally to the usual type. Characteristic vertical starch gel electrophoretic patterns of representative sera are shown in Fig. 1. Phenotype frequencies encountered within the two populations are shown in Table 1.

Immunoelectrophoretic analysis produced patterns concordant with the results of starch and polyacrylamide gels. Ouchterlony immunodiffusion of sera from indi-

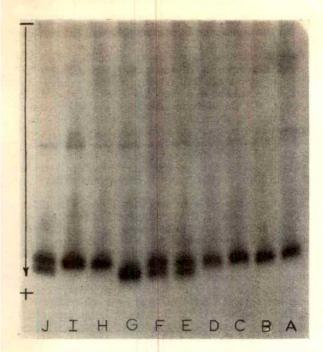

Fig. 1. Vertical starch gel representation of human serum albumin phenotypes. (A-D, H and I) individuals homozygous for allele AlA; (E, F and J) heterozygotes AlA!/AlA; and (G) a homozygote for the Algonkian variant, AlA!/AlA!.

viduals homozygous and heterozygous for the variant albumin and homozygotes for the common type developed precipitin arcs characteristic of immunological identity when tested against rabbit, goat and horse anti-human albumin antisera.

The presence of individuals homozygous and heterozygous for a fast-migrating albumin variant within the same populations (as in this case and ref. 1) and evidence from pedigree analysis^{1,2} indicate hereditary transmission through an autosomal, co-dominant, equally expressive allele to that in control of synthesis of the usual type of human serum albumin, AlA. Family and linkage analysis, now in progress, on the Ojibwa material should provide additional relevant information on the inheritance pattern of the variant albumin.

Table 1. DISTRIBUTION OF ALBUMIN TYPES IN POPULATIONS OF NORTH AMERICAN INDIAN

Assuming that the electrophoretically identical variants encountered among the Naskapi–Montagnais¹ and the Ojibwa–Blackfoot populations, as well as the Cree variant³, constitute the same molecular species of serum albumin, we have provisionally designated the controlling allele as AlAlgonkian (AlAl). Such a designation utilizes the linguistic affinity uniting these populations¹ and has the merit of emphasizing probable genetic relationship between the constituent populations. The sporadic occurrence of the Algonkian variant among Siouan, Athabaskan and Tlingit-speaking peoples¹ is best attributed to gene flow at the periphery of the extensive territory inhabited by Algonkian-speaking peoples in Canada and the northern United States.

We thank Drs G. Albin Matson and C. S. Chenault for the Blackfoot and Ojibwa sera and T. Hoff, C. Olson and C. Meldahl for technical assistance. This work was supported in part by the Graduate School of the University of Minnesota.

PATHOLOGY

Neural Mechanism in Induction of Dioestrus and Tumour in the Androgen Sterile Rat

THERE is accumulating evidence of a connexion between hormone imbalance and tumorigenesis. A gonadotropin imbalance in the endocrine environment has been related to the development of granulosa cell tumours of the ovary¹, and to the induction of mammary gland tumour in mice in which prolactin release is a feature of the

experimental hormonal environment2.

When chemical carcinogens were administered for prolonged periods to induce mammary gland tumours in mice, Jull described their effects on target tissues as mimetic of oestrogen or progesterone³. Studies of more immediate effects of chemical carcinogens have shown decreased prolactin content of pituitaries of lactating rats after the administration of 3-methylcholanthrene (3MC) (ref. 4), which was found, together with 9,10-dimethyl-1,2-benzanthracene (DMBA) and 3,4-benzpyrene (BP), to initiate mammary secretion and maintain lobulo-alveolar structure in oestrogen-primed female rats. The ability of these three carcinogens to elicit mammary cancer may depend partially on stimulating prolactin secretion⁵.

A direct correlation between carcinogen-associated endocrine effects and the development of a tumour has not been reported. In this communication, we give evidence of a possible association between changes in the endocrine environment and the development of tumours. Our data are based on investigations of tumorigenesis in rats, aspects of which we have reported previously (ref. 6 and paper at symposium on Biorhythms in Experimental and Clinical Endocrinology, Florence, 1966, to be pub-

lished).

In the basic experiment, 50 day old androgen sterile and control Sprague-Dawley female rats were given a single intragastric dose of either DMBA administered according to the regimen of Huggins et al.7 or the solvent vehicle. Androgen sterility as defined by Barraclough* was induced by a single subcutaneous injection of 1.25 mg of testosterone propionate at 5 days of age. Body weight and the state of the vaginal cycle were monitored on a regular basis. For each animal vaginal smears were taken daily from the day the vagina opened until necropsy. Individual animal weights were noted weekly from 21 days until necropsy; more frequent observations were made during treatment. Necropsies were conducted either 3 or 100 days after carcinogen administration, and particular attention was given to the mammary glands, adrenals, pituitary, ovaries, uterus and vagina. Animals necropsied 3 days after carcinogen had been given established adrenal necrosis as a possible response to carcinogen. and so a finding at necropsy 100 days after carcinogen.

of adrenal cortical calcification or fibrosis with little or no regeneration of the reticularis, was interpreted as an indication of adrenal necrosis after administration of the carcinogen*. An additional reflexion of the endocrine environment was the functioning of the mammary glands, shown by the presence of milk or the histological observation of lobulo-alveolar development and secretion from necropsy preparations 100 days after carcinogen. The vaginal response of dioestrus was considered to have been seen if the smears indicated dioestrus within 4 days of treatment and if the smears indicated oestrus for each of the 3 days before treatment; if smears did not indicate oestrus for each of these 3 days, the response was considered to be indeterminate. The vaginal response noted in the daily vaginal smears is confirmed by histological examination of the vaginal wall 3 days after the carcinogen. There is absence of keratinization, and neutrophiles are found in the vaginal mucosa and lumen. The endometrium shows a related response in that the lining epithelium is markedly reduced in height and there is depletion of stromal mucopolysaccharide.

In considering the associations between the endocrine environment and tumorigenesis, comparisons among the treatment groups do not provide for distinguishing responses which result from the carcinogen independent of tumour development from those that are more directly associated with tumours. To consider associations within treatment groups may be more instructive. The number of tumour-free animals may be so small, however, that the contrast of endocrine responses on the basis of tumour development is uninformative. In our basic experiment, for example, only two of the twenty-five control animals treated with carcinogen failed to develop either mammary gland or ovarian tumours before necropsy at 100 days after treatment with carcinogen; it is not informative that no association with tumour development was seen with respect to these data. The androgen sterile animals treated with carcinogen are more informative in that seven out of twenty-three failed to develop tumours. Although the number of tumour-free animals is small, it is still worth while examining the data for possible associations.

Results are given in Table 1. Changes which may indicate an immediate endocrine response to the administration of carcinogen are considered with reference to tumour development. The changes considered are vaginal dioestrus in previously constant oestrus animals, adrenal damage and change in body weight during the 3 days after carcinogen administration. The development of milk secretion by 150 days is included.

A hundred days after treatment, sixteen of the twentythree treated androgen-sterile rats (TD) had developed tumours and eleven of these had developed mammary gland tumours while five had granulosa cell tumours of

* Vaginal response in constant oestrus rats indicates arrest of keratinization and neutrophil migration, or mucification, within 96 h of administration of DMBA at age 50 days, as shown by daily vaginal smears. The vaginal response is considered to be indeterminate in animals not in vaginal oestrus for the 3 days before administration of carcinogen.

the ovary. In no case were both mammary gland and ovarian tumours found in one rat. None of the untreated androgen sterile rats (TV) developed tumours.

Vaginal response is positively associated with subsequent development of tumours ($\chi^2 = 6.03$, P = 0.007, TD necropsy at age 150 days). All five animals with ovarian granulosa cell tumours showed the vaginal response. Of the eleven rats that developed mammary gland tumours, seven showed the response, two gave no response, and response was indeterminate on the other two. Of the seven tumour-free animals, one showed the response. An alternative expression of the association is that twelve of the thirteen responders developed tumours but only two of the seven non-responders developed

No association with tumour development is demonstrated in the case of the development of lactation or in the immediate response to the carcinogen as reflected in the change in body weight and adrenal damage. These results do not necessarily indicate a lack of association, but they do indicate the lack of a strong association with tumour development. Huggins and Morii did not consider adrenal damage a prerequisite to mammary cancers. There are several effects of treatment with carcinogen, and the results reported here may be interpreted as showing that the effects are not strongly associated among themselves and that the tumour-free rats were not completely immune to the effects of the carcinogen.

It would be interesting to correlate tumour development with changes which could only be determined by killing the animals immediately after giving the carcinogen. If vaginal response is considered to be a predictor of tumour development, in that there is a positive association of this response with the subsequent development of tumours, it is possible to associate indirectly observations made at necropsy 3 days after giving carcinogen with eventual tumour development. We can examine their distribution in animals which did or did not show the vaginal response. Although such correlation is tenuous, it is worth considering. In our experiment, four of the twenty-two androgen sterile rats (TD) that were necropsied 3 days after carcinogen had been given gave no vaginal response. Results of other responses for animals necropsied at 53 days, grouped according to vaginal response, are given in Table 2. It is of interest that the organ weights for the non-responding group match corresponding weights of untreated androgen sterile animals necropsied at the same age.

Table 2. CARCINOGEN-INDUCED CHANGES ACCORDING TO VAGINAL RESPONSE
IN ANDROGEN STERILE RATS NECROPSIED AT 53 DAYS

Statistical significance was evaluated from t ratio using pooled variance estimate; comparisons of organ weights were made from logarithms of the observed weights.

* Response indeterminate on one animal.

† Mean \pm standard deviation.

In TD animals necropsied 3 days after the carcinogen was given, the vaginal response is related to a decrease in weight of pituitary, ovaries and uterus. It is not clear whether the results can be accounted for as unrelated, separate target organ responses or whether they are related through the initiation of a cycle. The association of losses in organ weight with vaginal dioestrus suggests that the vaginal response is not an isolated peripheral effect of the chemical carcinogen but that it may be related to release of hormones by the pituitary and ovaries. If this is so, it is plausible that the endocrine effects are to a large extent the result of central action of the DMBA; action on the hypothalamus, in particular,

is suggested.

A possible central effect is supported by additional con-The finding of augmented lactogenesis in androgen sterile animals 100 days after treatment with carcinogen⁶ implies a sustained release of prolactin by the pituitary and is consistent with a neural action of DMBA. Second, the interruption of vaginal keratinization followed by dioestrus and proestrus (androgen sterile rats) after administration of DMBA resembles the vaginal response to progesterone in persistent oestrus rats¹⁰ and in androgen sterile rats¹¹. The nervous system may be involved in this response¹². Barraclough has proposed that treatment with progesterone lowers thresholds of excitability within the hypothalamus of sterile rats13. By analogy, the carcinogen DMBA may affect the hypothalamus. An additional support is the release of pituitary prolactin within 16 h of administration of the carcinogen 3MC. If the effect of DMBA is similar in time, our finding that the vaginal response is delayed for approximately 48 h is at least consistent with the possibility that endocrine effects are largely secondary to a central effect.

The endocrine effect of vaginal response was found to be associated with tumorigenesis, and we have used this association in considering the possibility that other endocrine effects are similarly associated with tumour development, and the results are suggestive of such associations, but are not conclusive. If the immediate endocrine effects, and the vaginal response in particular, arise chiefly in response to a central neural effect of the carcinogen, then a plausible inference from the association between vaginal response and tumour development is that the suggested neural effect of the carcinogen is a significant factor in

tumorigenesis. This work was supported by an American Cancer Society institutional research grant and the California Institute for Cancer Research. Increased Incidence of Carcinoma induced by DMBA in the Hamster Cheek Pouch in response to Vitamin A

VITAMIN A, when administered topically or systemically in high doses, retards the growth and inhibits the induction of benign and malignant tumours1-3. When it is applied locally, vitamin A inhibits the development of tumours of the cervix and vagina of hamsters induced by 9,10-dimethyl-1,2-benzanthracene (DMBA), but has

no protective effect on the perineal skin1. Topical application of excessive vitamin A, however, is known to cause epithelial hyperplasia and mild atypicality, disorientation of the basal layer4-6, rapid epithelial proliferation7 and mucoid metaplasia, with the formation of glandlike structures8,9; and an increased incidence of avian leukosis has recently been reported in response to excess vitamin A (ref. 10). We describe here the effect of topical hypervitaminosis A on the induction by DMBA of careinoma in the hamster cheek pouch.

The right cheek pouches of thirty-five Syrian golden hamsters aged 2 months were painted three times a week with one of the following substances dissolved in liquid paraffin: 0.5 per cent DMBA (fifteen animals, DMBAgroup); 0.5 per cent DMBA combined with 10 per cent vitamin A palmitate (E. Merck AG, Darmstadt; 1 g= 1.7×10^6 IU) (fifteen animals, DMBA-A-group); or 10 per cent vitamin A palmitate (five animals, A-group). Half the animals from each group were killed after 9 weeks, and the remainder after 11 weeks.

After 9 weeks the pouches of all animals in the DMBAgroup showed areas of irregularity of the mucosa and a few small papillomatous tumours. Histologically, lesions included epithelial hyperplasia with very prominent hyperkeratosis, benign papillomata, intra-epithelial carcinoma, and occasional foci of early infiltrating squamous cell carcinoma.

The pouches of all animals of the DMBA-A-group revealed diffuse irregularity of the mucosa and many tumours which were larger, more numerous and more irregular than those in the DMBA-group. Histologically, the most outstanding feature was the presence of many feet of intra-epithelial carcinoma and infiltrating squamous cell carcinoma. There was mucoid metaplasia of some tumour cells with the appearance of gland-like structures in the infiltrating tumours. Non-tumorous areas showed generalized epithelial hyperplasia, but the marked hyperkeratosis found in the DMBA-group was absent, and the epithelium was covered by a thin layer of pale staining keratin.

The pouches of all animals in the A-group revealed areas with marked acanthosis, hyperplasia and mild pleomorphism. In most areas there was only a thin layer of pale staining keratin. In some areas, however, the keratin was absent.

The animals killed after 11 weeks of painting revealed similar lesions. There was, however, a striking increase in the number and size of tumours in the DMBA-A-group as compared with the DMBA-group. The pouches of the A-group showed marked acanthosis and focal epithelial atypicality. No foci of mucoid metaplasia, however. were present. Table I summarizes our results.

ble 1. RESULTS OF LOCAL TREATMENT OF HAMSTER CHEEK POUCHES WITH DMBA, VITAMIN A, AND A COMBINATION OF BOTH SUBSTANCES Table 1. 11 weeks

9 weeks Group DMBA

Few small papillary tumours, histologically ranging from benign papillomas to intraepithelial carcinoma, and only occasional small foci of infiltrating carcinoma.

DMBA-A Numerous, irregular tumours. Histologically, many foci of intra-epithelial and invading carcinoma.

A Histologically, foci of mild epithelial hyperplasia and pleo-

thelial hyperplasia and pleo-morphism.

Scattered slightly irregular tumours. Histologically as at 9 weeks, but more foct of infiltrating carcinoma.

Many large, irregular tuneours.
Histologically, many careinomas with extensive infiltration.
Histologically, foel of marked acanthosis and pleomorphism.

Squamous cell carcinomas induced in hamster cheek pouches by DMBA are known to appear 10-11 weeks after the initial painting, and pre-malignant lesions after 7-8 weeks11. In our experiments, tumours appeared after 9 weeks of painting with DMBA only, but we found many more and larger tumours at the identical stage in the These differences were even more DMBA-A-group. obvious after 11 weeks.

The mechanism underlying the earlier development of malignant tumours in the DMBA-A-group may be related

to an increased mitotic index, rapid epithelial proliferation and altered differentiation of epithelial cells as reported after the topical application of moderate quantities of vitamin A (refs. 4-9). This may cause the malignancy induced by DMBA to appear earlier and more extensively in epithelium altered by a moderate excess (10 per cent solution) of vitamin A. Other factors which may be involved include altered permeability of cellular and subcellular membranes 12,13 and the release of lysosomal proteolytic enzymes induced by vitamin A (refs. 14, 15).

Non-self-maintaining Kinetics of Proliferating Blasts in Human Acute Leukaemia

THERE is still uncertainty about the cytological characteristics of stem cells, their production and kinetics. As far as pathology is concerned the acute leukaemias are characterized by the presence and multiplication of the youngest recognizable cells of each haemopoietic line; these are the blasts. The identity of the blasts and their histogenetic connexions with stem cells are not known, and the possibility that acute leukaemia blasts are stem cells has recently been raised 1-3. These blasts are often similar to the normal parent cells of the various haemopoietic lines and can therefore be identified as myeloblasts, lymphoblasts or monoblasts. Sometimes, however, their features are even more undifferentiated and/or atypical, and thus the definitions stem cell leukaemia, haemocytoblastic acute leukaemia, acute histioleukaemia.

Taking the leukaemic blast population as a whole, allowance must be made for the fact that only some of the blasts are able to proliferate as shown before4. Clearly the problem can be posed more precisely by considering only those of the blasts which multiply. If an acute leukaemia blast population is divided into classes on the basis of cell diameter, it is possible to isolate a class of large blasts, the labelling index of which is similar to that of normal bone marrow blasts4. The class of large and normally proliferating blasts constitutes less than 10 per cent of the whole population when this population is in a relatively steady state, but this can rise to 15-20 per cent when the population is expanding rapidly. Can this class of proliferating blasts be taken as a class of stem cells? Cronkite recently pointed out that "one cannot be too certain on this issue and much further work is needed to answer the question"3.

We believe that one way of tackling this problem is to assume that if the normally proliferating blasts are stem cells for the entire acute leukaemia population, they should show the kinetic features of a self-maintaining cell population. We have therefore studied four patients with untreated acute myeloblastic leukaemia by means of in vivo pulse labelling with tritiated thymidine (0.2 µc./g of body weight, specific activity 2 c./mmole). In all four cases, the blast population constituted more than 90 per cent of nucleated cells in both bone marrow and peripheral blood. In the days before and during the experiment, clinical and haematological conditions were constant. The bone marrow and peripheral blood were sampled 1 h after injecting the tracer and thereafter at different times. The autoradiographic preparations were made with a technique described before \$\frac{4}{3},6-8\$.

Blast cells always varied considerably in size, and cell diameters ranged in case 1 from 8 to 21µ, in case 2 from 7 to 16.5μ , in case 3 from 8.5 to 19.5μ , and in case 4 from 8 to 19.5\mu, that is there was at least a doubling in each case. This variation is much greater than the differences in diameter—shown to be 20 per cent—seen in the same types of cell in S and G_1 (ref. 9). We were thus dealing with real cell heterogeneity which was only slightly dependent on the different phases of the cell cycle. The blast population was divided into three equal classes according to diameter. The percentage distribution of the cells in the three classes was on average: large blasts 9 per cent of the whole population; medium blasts 51 per cent; and small blasts 40 per cent. In all classes, cell distribution was constant throughout the experiment.

	24	8.2	11.2	6.6	10.4	22.7	35.0	22.5	21.1	
	70	9.3	9.0	9.1	9.5	23.2	31.0	23.6	21.2	

Labelling indices were determined by counting from a minimum of 300 cells, for the large blasts (representing the smallest part of the population) to a maximum of 2,000 cells. The mean grain count was estimated by counting the grains on a number of labelled cells varying from at least seventy (large blasts) to more than 200 cells

As shown in Table 1, 1 h after injecting the tracer we observed a high labelling index in the bone marrow in all large blasts (values about 40 per cent, that is similar to those of blasts in normal bone marrow); a very low labelling index in the medium sized blasts and no evidence of labelling at all in the small blasts. Between 10 and 17 h the mean number of grains/cell halved in all cases. This means that during this period the cells which were in S at the time of pulse labelling completed this phase, passed the G2 phase and underwent mitosis. After this first division, there was a sharp fall in the labelling index in the class of large blasts (on average from 40 per cent to 16 per cent) and this was accompanied by an increase of the labelling index of the medium sized blasts and by the appearance of labelled small blasts. On subsequent days the labelling index of the large blasts remained almost stationary at low values or decreased slightly more. This means that many more than 50 per cent of the daughter cells become small after division and come out of the class of large blasts for good, or at least for a period of time longer than the generation time. The class of large blasts does not therefore behave as a pool of self-maintaining cells but rather as a normal multiplicationmaturation compartment.

Table 2. CELL FLUXES IN AN AGUTE LEUKAEMIA BLAST POPULATION (MEAN VALUES FROM FOUR CASES)

	Large blasts	Medium blasts	Small blasts
Relative number (N)	88	506	406
Labelling index $\left(\frac{Ns}{N}\right)$	42.3%	1.6%	0%
Proliferation rate $\left(\frac{Ns}{Ts}\right)$	2-32	0.52	0
Influx (\overline{Ki}) Sum of the proliferation		2.94 = 2.84	1.92
Total influy in non-prol	iferating compartme	ant = 4.86	

Ns, number of cells in DNA synthesis; Ts, DNA synthetic period = 16 h; Ki, number of new labelled blasts appearing/h in medium and small blasts.

We were also able to quantify the kinetics of proliferating blasts as follows. In all four cases we evaluated fluxes between the various classes of blast in the first 10-17 h after the precursor was injected; we used a modification of the method already used for normal bone marrow10. We considered: (a) the labelling indices of the various classes at 1 h and after the first division; (b) the rate of appearance of new (medium and small) labelled blasts in the bone marrow in each hour during the period considered; (c) cells discharged into the peripheral blood in the same

period. This evaluation was based on the number of grains lost from the bone marrow/1,000 cells, divided by the mean number of grains/labelled cell which appeared in the peripheral blood; and (d) the duration of the S phase of proliferating blasts this was evaluated in one case only, in which it was possible to take repeated bone marrow samples. On the basis of the progression of the percentage of labelled mitoses, the duration of S was found to be 16 h, which agrees with previous evaluations for acute leukaemia2,11; we adopted this value for all cases. Table 2 shows the values which we obtained.

The rates of proliferation, calculated on the basis of the labelling indices and the duration of S, are much lower than the total influx into the non-proliferating part of the population as calculated from the number of cells which appeared in the non-proliferating part of bone marrow and peripheral blood. This result also suggests that the pool of proliferating blasts does not behave as a self-maintaining system.

There is thus some evidence that even if a comparatively small section of the blasts with the same proliferative activity as normal marrow blasts is isolated from the whole blast population in myeloblastic acute leukaemia, its kinetic behaviour is not what would be expected from stem cells. It is rather the behaviour of a system which has to be continually replenished in cells from another part of the population.

Substrate Limiting Melanogenic Inhibitor in Malignant Melanomas

The presence of a heat stable, tyrosinase-inhibiting factor in various malignant melanomas has recently been reported¹⁻⁴. The reported inhibitor(s) has been partially purified and its mode of action has been determined to be competitive. Although it was not determined whether competition was with enzyme or substrate, the presence of a tyrosine residue within this factor seemed to suggest competition with substrate. We report here the presence of a separate, heat labile inhibitory substance within malignant melanoma tissue which is competitive with tyrosinase, that is, it competes with tyrosinase for the substrates tyrosine and 3,4 dihydroxyphenylalanine The independence of this inhibitory activity (dopa). from either added pyridoxal phosphate or α-methyldopa, from ATP, and furthermore, its absence in normal hamster liver, provides evidence that it is not due to either tyrosine or dopa decarboxylase or transaminase, or in vitro protein synthesis.

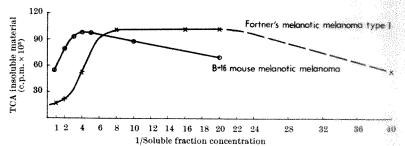

Fig. 1. Tyrosinase radio-assay of Fortner's melanoma soluble fraction at various concentrations.

We first obtained evidence for the presence of this substance while studying the total amount of melanin formed under low substrate conditions using varying concentrations of the soluble fraction, obtained after centrifuging at 105,000g for 1 h, of the homogenate of Fortner's melanotic melanoma type No. 1 (1 g tumour to 5 ml. 0.25 molar sucrose) or of B-16 mouse melanoma (1 g tumour to 10 ml. 0.25 molar sucrose). When various dilutions of the soluble fraction were incubated at 30° C for 16 h in 0·1 molar phosphate buffer, pH 6.8, with 0.27 $\mu c.$, 2.8×10^{-8} molar DL-tyrosine-2-14C, along with 92 μg/ml. chloramphenicol^{6,7}, the presence of an internal inhibitor became apparent (Fig. 1). Only with more dilute preparations is the total amount of melanin formed (TCA insoluble material) approximately proportional to the concentration of the enzyme present in the soluble fraction (Fig. 1); as the enzyme preparation becomes highly concentrated, the amount of melanin synthesized becomes inversely proportional to preparation concentration. Furthermore, as shown in Table 1, the 1:1 undiluted soluble fraction converts less tyrosine to melanin than a 1:20 dilution. The addition, to the 1:1 incubation, of an original amount of soluble fraction after the completion of 16 h and further incubation for 4 h fails to increase the amount of melanin formed, while the addition of an original amount of tyrosine-14C increases the amount of melanin formed. Thus all available tyrosine has already been converted to TCA insoluble material, and it is apparent that some of the original tyrosine is now unavailable for melanin synthesis, although active tyrosinase is still present. Chromatography of the TCA supernatant from the 1:1 incubation, using either paper or Gelman silicate thin-layer

Table 1. TYROSINASE RADIO-ASSAY OF FORTNER'S MELANOMA SOLUBLE FRACTION OF 1:1 AND 1:20 DILUTIONS

Incubation 1:201:1+S - 1:20+S - 1:1+E - 1:20+ECPM of TCA precipitate (duplicates) $14,600 \\ 15,400$

S, Substrate added; E, soluble fraction added.

chromatography media and water saturated phenol, yields two radioactive peaks. One of these corresponds to a standard tyrosine solution (probably representing D-tyrosine-14C); the other has an R_F 0.3 under the described conditions and represents a reaction of this inhibitor with tyrosine-14C. Chromatography of the TCA supernatant from the 1:20 incubation yields a tyrosine peak, but only a trace peak at R_F 0.3. Preliminary studies using gel chromatography indicate this inhibitor has a molecular weight under 10,000. While the presence of a low molecular weight enzyme which utilizes tyrosine or dopa as substrate cannot be excluded at this time, any substance which serves to lessen melanin formation through substrate limitation belongs in the category of substrate limiting melanogenic inhibitor. The enzyme exhaustion observed after incubation for 16 h with 1:20 dilution remains to be clarified in relation to enzyme stability in dilute solution, the recently described enzyme directed inhibitor, and reaction inactivation.

The present finding of this substrate binding inhibitor should be considered in the future investigation not only of tyrosinase activity but also of disturbed melanogenesis, particularly because albino melanocytes⁸ and amelanotic melanoma cells, have been shown to contain tyrosinase and to undergo melanization of their premelanosomes if sufficient free L-tyrosine is made available in vitro7. In addition, the recent report of Demopoulos10 on the selective inhibition and regression of malignant melanomas by tyrosine deprivation must be further evaluated together with these findings.

This investigation was supported in part by grants from the National Cancer Institute and from the National Institute of Arthritis and Metabolic Diseases, US Public Health Service. M. COOPER

Identification of 3,4-Dimethoxyphen-ethylamine from Schizophrenic Urine by Mass Spectrometry

THE occurrence of the "pink spot" in the urine of schizophrenies was first reported by Friedhoff and van Winkle¹, who tentatively identified the substance as 3,4-dimethoxy. phenethylamine (3,4-DMPEA). Subsequent interest in this amine is linked to the possibility that its formation may result from an aberration in the metabolism of the endogenous amine, dopamine, as either a resultant or aetiological factor in mental disorders². Reports of both confirmatory3-7 and conflicting8-14 nature have appeared with respect to the identity and origin of the "pink spot" 15,16. The methods which have been used to isolate and identify the "pink spot", solvent extraction, ionexchange chromatography, paper and thin-layer chromatography, counter-current distribution and various colour reactions, have not provided unequivocal identification. Much of the controversy originates from the non-specificity of chromatographic separation and the complexity of amines present in human urine. Indeed, several "pink spots" occur in urine extracts which are isographic in one or more of the solvent systems used to isolate the 'pink spot''

In the work reported here we have applied a new technique for both the isolation and identification of the "pink spot"17. The initial extraction and chromatography was performed as follows: urine was obtained from two female schizophrenics daily for 5 days; the collections were made in 1 normal hydrochloric acid/toluene to a final pH of 1 and stored frozen; the urines were pooled

(volume 8 l.), the pH adjusted to 10 with 5 normal sodium hydroxide, extracted with 12 l. of methylene chloride, the organic solvent removed in vacuo, the residue suspended in 10 ml. of methanol and clarified by centrifugation. A portion (5 ml.) of the extract was streaked on Whatman No. 3 paper and developed in butanol, acetic acid and water (4:1:1) by descending chromatography. A band between R_F 0.52 and 0.66 which corresponded to 3,4-dimethoxyphenethylamine (R_F 0.58), and which gave on a guide strip a pink colour with ninhydrin/Ehrlich, was cut out and eluted by descending chromatography with 0.05 normal hydrochloric acid. The extract from the paper was chromatographed on silica gel plates in several solvent systems revealing at least seven pink spots. The optimum resolution was obtained with nitroethane, acetic acid and water (90:24:12) as shown in Fig. 1.

The area corresponding to 3,4-DMPEA (Fig. 1B) was extracted with acetone-water (5:1), centrifuged and the supernatant was reacted with 5-dimethylaminonaphthalenesulphonylchloride in the presence of excess sodium bicarbonate to form the "dansylamine" derivative. After 4 h, an excess of water was added and the dansyl derivative was extracted into ethyl acetate. The solubility in organic solvents and the intense yellow to blue fluorescence on ultraviolet irradiation make the "dansylamines" ideal The two-dimensional for thin-layer chromatography. chromatogram of the dansylated products formed from the components in "pink spot B" (Fig. 1) is shown in Fig. 2. The principal spot, which exhibited a bright yellow fluorescence, corresponded closely with the migration of authentic dansyl-3,4-DMPEA and was clearly separated from the dansyl derivatives of 2,3- and 2,5-DMPEA and The "dansyl-DMPEA" p-methoxytyramine. was extracted into ethyl acetate and the concentration estimated fluorometrically (Aminco-Bowman, uncorr.; activation 340 mµ; emission, 510 mµ). A minimum value which is uncorrected for losses during isolation of 4 $\mu g/g$ creatine was obtained.

The dansyl derivative was then analysed by mass spectroscopy (Fig. 3). The chief component had a mass of 414 which corresponded exactly with that obtained with authentic dansyl-3,4-DMPEA. The remaining pattern of fragmentation of both the unknown and authentic dansyl derivatives was identical. Although other structures can be devised for a mass of 414 they are, in light of the other properties of the unknown, quite untenable. Thus the isolated material is certainly a DMPEA. 2,3-, 2,4-, 2,5-, 2,6- and 3,5-isomers were eliminated on the basis of their chromatographic behaviour. It is most probable on the basis of colour reactions and chromatographic behaviour that the material is the 3,4-substituted amine.

This finding demonstrates that low concentrations of dimethoxyphenethylamine were present in the schizo-phrenic urine sample examined. The "pink spot" band, isolated by paper chromatography, however, consisted of at least seven different compounds as shown by subsequent thin-layer chromatography. DMPEA was thus only a minor constituent of "pink spot" in this urine sample, and its ultimate origin from either a dietary source, bacterial metabolism or endogeneous metabolism and any relationship between its presence in urine and mental disease remains to be investigated using a specific method such as described here. Kuehl and co-workers¹⁷ have recently carried out such a study on the occurrence of 3,4-dimethoxyphenylacetic acid in urine. They used a combination of gas chromatography and mass spectrometry and have reported 3,4-dimethoxyphenylacetic acid in both normal and schizophrenic urine.

PHYSIOLOGY

Origin of Delayed Implantation in Marsupials

Much work has been done on delayed implantation in macropod marsupials and it is now known that the phenomenon is widespread through the family¹⁻⁷. Sharman has shown that the average length of pregnancy in the red kangaroo (Megaleia rufa) is 33.17 days and that post-partum oestrus occurs about 2 days after parturition and the entry of the neonatus into the pouch. Although copulation will now occur, the new foetus-the species is monovular-will remain in one of the two uteri in the blastocyst stage for as long as the pouch young is suckled. If the neonatus is removed from the pouch, lactation is arrested, the quiescent blastocyst starts to develop, and the next generation is born after about 31 Usually, the "joey" or pouch young remains in the marsupium for about 236 days and it is not unusual in some macropod species for a young-at-foot to be fed from one nipple, a naked neonatus from another while a third generation, in the form of a blastocyst, lies dormant yet viable in one of the uteri. This species inhabits arid and semi-arid country over a vast area of Australia.

Certainly such an extraordinary mechanism could not arise, nor would it be retained, unless it conferred great benefit on the species that possess it. Waring4 said that "the selective advantages of delayed implantation in the large kangaroos which traverse great distances can be easily imagined. The doe is known to discard her joey when harassed by predators and the same circumstances may separate her from her buck . . . the selective advantage . . . for the quokka [the small scrub-dwelling Setonix brachyurus] is not so obvious and of course we may well take the view that it was developed for other circumstances and is now just built into the gene structure". Sharman3, too, said the emergence of a second offspring without preliminary mating is "presumably of some adaptive significance if the animals, in times of sparse grazing, are dispersed over a wide area". Ealey^{5,8} and Sadleir, who worked with kangaroos in the arid northwest of Western Australia, showed that the post-partum mating and its resultant quiescent blastocyst probably benefited both Macropus robustus (personal communication from Ealey) and M. rufa by enabling repeated reproduction at appropriate times.

These observations, however valid in themselves for xerophilous animals, do not give us an explanation of the general utility of the post-partum oestrus and delayed implantation in the macropod marsupials as a whole. The history of aridity in much of Australia is relatively brief and, judged by its wide distribution in the Macropodidae, the history of the post-partum oestrus and delayed implantation is very long.

Several authors are careful to point out that in most species in which delayed implantation is apparently controlled by lactation, the gestation period is slightly shorter than one oestrous cycle and one has gone so far as to suggest that, while it is of benefit to the species, "post-partum ovulation may be merely an unavoidable by-product in marsupials that have a gestation period shorter than the oestrous cycle". More recently, too, it has been concluded that lactation-controlled delayed implantation may have evolved independently in a number of species in which the gestation period was extended and that it has "no special significance except that the mechanism prevents the occupation of the pouch by young of different ages" 10.

The length of the oestrous cycle is probably very adaptive. The important event is surely the post-partum oestrus that (as, for example, in the domestic mare) allows successful insemination to occur again soon after the emptying of the uterus. This means that the doe kangaroo is almost always pregnant but, because implan-

tation and development are delayed, little or probably no loss of mobility occurs.

From information already assembled¹¹ it can be seen that the post-partum oestrus and lactation-controlled implantation, or post-partum oestrus alone, is not restricted to marsupials inhabiting arid, periodically drought-stricken regions. Thus such animals include a small retkangaroo, the quokka which inhabits relatively lush, well-wooded areas; the tammar wallaby (Protemnodon eugenii), which lives in island scrubs; the red-necked wallaby (P. rufogrisea), which confines itself to heavy scrub or brush; the long-nosed rat-kangaroo or potoroo (Potorous tridactylus), an inhabitant of dense damp scrubs; the swamp wallaby (Protemnodon bicolor) which prefers damp valleys; the boodie (Bettongia lesueuri), a small nocturnal rat-kangaroo adapted to islands as well as deserts; and finally, the red kangaroo and the euro, both of which live in dry, periodically drought-stressed regions.

On the other hand, the grey kangaroo or forrester (Macropus cangaru), which inhabits well watered and sheltered country near the coasts, does not delay implantation. When the pouch young was removed during the season of increased breeding frequency (the warmer months September to March) the female usually returned to oestrus within 13 days and so quickly became pregnant again. If pouch life was not interrupted this lasted for about 312 days (compare 236 days for the red kangaroo in more hazardous circumstances). Also because of the relatively restricted peak breeding period each female forrester will usually produce only one joey each year¹².

These data show that lactation-controlled delayed implantation occurs in such phylogenetically different types as the giant red kangaroo and the small rat-kangaroos (for example, Bettongia) and in such ecologically diverse animals as the desert-dwelling euro, the coastal swamp wallaby, and the potoroo, which inhabits lush damp Tasmanian forests. Clearly, then, the phenomenon has greater significance than merely to replace pouch young lost by the bigger kangaroos in arid conditions. Rather, it can be said that the macropod stock was pre-adapted to deal with such losses because there seems little doubt that the mechanism is of greater antiquity than is aridity in most areas of Australia. True macropod kangaroos are known from the Miocene when members of the ferocious Thylacinidae (marsupial "wolves") were also present. The great diversification of macropods took place during the Pliocene during a "fluviatile regime"13. This was a period of widening pastures but, although rainfall was decreasing, Australia was not yet a place of widespread aridity.

The question, then, arises: what was the primary function of the mechanism? The most probable explanation is that macropod marsupials almost always produce only one offspring at a time, although in highly exceptional circumstances twins may be born. They are timid animals, invariably fleeing from danger and, with few exceptions, do not take refuge in hollow logs or burrows. The young-at-foot is always highly vulnerable, and the large pouch young is often lost, or deliberately unloaded by the doe in desperate flight. It seems likely, then, that predator pressure on timid, relatively defenceless, monovular animals has made for the evolution of the mechanism—perhaps more than once—in ancestral forms and its retention in a variety of modern macropods inhabiting a wide range of habitats. On this reckoning delayed implantation (but not the post-partum oestrus) has probably been lost in M. cangaru, and has arisen by convergence in the minute pigmy possum (Cercartetus concinnus).

That the herbivorous fauna of Australia was subject to widespread predation in, for example, the Pliocene is evident from an analysis by de Vis¹⁴, who found that about 5 per cent of some hundreds of bones were "pitted, scored, cracked, chopped and crushed" by teeth. In

historical times notable predators have been the wedgetailed eagle (Uroaetus audax), the dingo (Canis dingo), the Tasmanian wolf (Thylacinus cyanocephalus) and, in the case of the smaller wallabies and rat-kangaroos, the Tasmanian devil (Sarcophilus harrisii), the tiger-cat (Dasyurops maculatus) and no doubt others. Although a relatively rare sight today except in remote parts of the continent, the wedge-tailed eagle was one of the com-monest birds in the days of early European settlement (for example, Vancouver¹⁵); in fact, all these predators were formerly extremely plentiful. Furthermore, both the Tasmanian wolf and the devil inhabited the Australian mainland until relatively recent times.

Mechanism for the Exchange of the Calcium in Bone Mineral

THE exchange of the calcium in bone mineral with radioactive calcium and other bivalent metals has been studied in living animals1 and in vitro2, and various physical processes which lead to exchange have been suggested3. Little attention has, however, been paid to the process of exchange itself—that is, the chemical reaction by which the calcium on the surface of bone mineral is replaced by radioactive calcium or other metals.

Even in pure metals, the dissimilarity in potentials between the inner and outer sides of a crystal surface may cause the structure of the surface to differ from that of the interior4,5. Bone mineral, which is considered to be chiefly hydroxyapatite3, is markedly impure and contains not only water of hydration, but carbonate, citrate, magnesium, strontium, and traces of other elements, many of them on the crystal surface. In addition, one side of a crystal may be bound to the organic matrix, while other sides correspond to sections through different planes of the unit cell, and therefore differ not only from the side bound to organic matter but from each other as well. Moreover, extensive work on heterogeneous catalysis has shown that the surface is more dynamic than the interior, and lateral migration of different atoms over it leads to a continual fluctuation of the chemical composition on a submicroscopic scale.

It is therefore extremely improbable that the surfaces of bone mineral crystals have the same structure as the interior and equally improbable that there is any sharp

distinction on the surface between screw axis or columnar calcium ions of bone mineral or hydroxyapatite. These surfaces are therefore best pictured schematically, as in Fig. 1a. No attempt has been made to draw to scale either atoms or their distances from the dashed line, which represents the "average" surface.

Many of the familiar reaction mechanisms in chemistry begin with the addition of one atom or molecule to another. I suggest that the similar addition of a calcium ion to the surface of bone mineral, rather than the expulsion of a previously bound calcium ion, is the first step in exchange. In bone mineral, a radioactive ion from surrounding fluid would have much more chance of forming a bond with an oxygen atom, which is always accessible, than of striking a vacant calcium site. Most of the bonds formed, as shown in Fig. 1b, are unstable and immediately break up. A small proportion, however, may remain until the neighbouring calcium ion is ejected (Fig. 1c). The new ion then slips down to occupy the more stable position now available to it (Fig. 1d).

This sequence of events is plausible and in accord with present knowledge of the behaviour of crystals, and it is supported by striking indirect evidence obtained with zinc-65.

When used without carrier, zinc-65 reacts more rapidly and to a greater extent with defatted bone powder and anorganic bone than do calcium-47, strontium-85 and barium-133. Even in the presence of 2.5 mmoles/l. of calcium, almost 100 per cent of zinc-65 tracer is taken up by anorganic bone in 5 min^{7,8}. This is in great contrast to the effect of calcium in reducing the uptakes of strontium-85 tracer² and barium-133⁸. More rapid uptake of zinc-65 than of calcium-47 would scarcely be expected if the ratedetermining step were the removal of a calcium ion; it would be expected if the rate-determining step were the addition of a zinc-65 ion as in Fig. 2. Because zinc is more electrophilic than calcium, has a smaller ionic radius, and forms a more covalent bond¹⁰, the neighbouring calcium ion is released more readily than in Fig. 1, and is rapidly replaced by zinc-65.

In the presence of 2.5 mmoles/l. of stable zinc, the reaction appears to go even further. Not only does zinc replace calcium, but additional zinc may add on, possibly in the form of ZnOH+, as in Fig. 2e.

It may be objected that an alternative explanation of the behaviour of the zinc is possible: that it reacts with the bone mineral to form a zinc phosphate. When zinc-65 is used without stable zinc carrier, however, it is obviously

at too low a concentration to form a precipitate of zinc phosphate, and either adds on to the bone mineral or exchanges with it. With 2.5 mmoles/l. of zinc carrier, the possibility of the formation of a precipitate of zinc phosphate has been ruled out by experiments on the removal of the radioisotope which has been taken up by exchange, and by mcre detailed studies of the uptake of stable and radioactive zinc with time (my unpublished

It is likely that the fluoride ion exchanges with the hydroxyl ion in hydroxyapatite and 32PO₄3- with surface PO₄3- by similar addition mechanisms.

Fertilization and Embryonic Loss in Sheep after Insemination with Deep Frozen Semen

Although there are reports of satisfactory lambing after artificial insemination with frozen ram semen1-4, most investigators have obtained disappointing results (reviewed by Emmens and Robinson⁵ and Sadleir⁶). It has been claimed, that frozen ram spermatozoa penetrate to the cranial part of the cervix more slowly than those from fresh semen. In an experiment⁸ with a limited number of animals, cervical insemination yielded only unfertilized eggs (eight ewes), and although after tubal insemination fertilized eggs were recovered from all three ewes examined, only two out of seven ewes lambed. We have conducted two experiments with frozen semen—the first at the McCaughey Memorial Institute, Jerilderie (Table 1) and the second on a private property at Yass, NSW (Table 2).

Semen was collected from mature merino rams by means of an artificial vagina. Ejaculates of good initial motility were pooled and diluted 1:1 at 30° C with a hypertonic ($\Delta = -0.90^{\circ}$ C) egg yolk-citrate-raffinose diluent, containing 3 per cent glycerol. Semen pellets (0.03 ml.) were prepared on dry ice, and stored in liquid

nitrogen for 4-12 weeks. The pelleted semen was thawed in 2.6 per cent sodium citrate (2:1) at 37° C and used for insemination within 10 min.

Four methods of insemination were used. For cervical inseminations 0.30 ml. of thawed semen $(120 \times 10^6 \text{ motile})$ spermatozoa) was deposited into the entrance of the cervix of ewes 10-25 h after the onset of oestrus. "Deep" cervical insemination was carried out by traction on the cervical papilla with forceps permitting semen deposition 1-3 cm inside the cervical canal. Uterine and tubal inseminations, following laparotomy, were performed on most of the ewes within 6 h (range 1-8) after ovulation. In experiment 2, an additional eight ewes were inseminated just before ovulation. For uterine insemination 0.1 ml. of thawed semen $(40\times10^6$ motile spermatozoa) was deposited into the cranial region of the appropriate uterine horn(s). Tubal inseminations were achieved by depositing 0.05 ml. of thawed semen $(20 \times 10^6 \text{ motile})$ spermatozoa) into the ampulla of the appropriate fallopian tube(s). Rates of fertilization were determined by egg recovery and examination for cell cleavage 48 h after either uterine or tubal inseminations and 60 h after Sperm transport through the cervical insemination. genital tract of the ewe was examined by flushing the fallopian tubes of three ewes at 3, 6, 12 and 24 h after cervical insemination 10.

In experiment 1 (Table 1), fertilization rates after cervical insemination with frozen semen were low (25 per cent of eggs or 31 per cent of ewes fertilized). In a concomitant experiment performed by T. D. Quinlivan (personal communication) using sheep from the same flock, 80 per cent of eggs were fertilized after cervical insemination with fresh undiluted semen $(100\times10^6$ spermatozoa). A mean of only twenty-four spermatozoa from each fallopian tube was recovered from twelve ewes after cervical insemination with frozen semen. number is very low compared with that observed after natural mating11 or artificial insemination with fresh semen¹⁰ when a population of several thousands is usually found. There were no differences between the four times of sperm recovery. The results indicate that an impaired pattern of sperm transport through the genital tract of the ewe was the principal cause of low fertilization rates after cervical insemination with frozen semen. Primary failure of sperm transport probably occurred in the cervix. This claim is supported by the results of experiment 2 (Table 2) where "deep" cervical insemination with frozen semen was markedly superior to the normal

Frozen ram semen can produce high rates of fertilization when the cervix is by-passed with the uterine insemination technique. This was first shown in experiment I and subsequently confirmed in experiment 2 with egg fertilization rates of 88 per cent and 93 per cent, Tubal inseminations were less successful. respectively. Despite the finding of a high proportion of ewes with fertilized eggs in experiment 2, only 34 per cent did not return to service within 22 days of insemination, which implies that normal development of the embryos failed in some 64 per cent of the ewes containing fertilized eggs.

Such a high rate of embryo mortality, however, may not be entirely the effect of freezing. It is possible that

some eggs were "aged" at the time of fertilization (review by Salisbury¹²), although in eight ewes inseminated just before ovulation the rate of non-return (38 per cent) was not significantly higher than that for the remaining sixty ewes (33 per cent). It is also possible that the technique of uterine insemination caused changes in the environment of the genital tract, so as to impair survival of the embryo. In these preliminary experiments, uterine insemination with fresh semen was not examined. Lopyrin et al.13, however, have obtained normal pregnancy after uterine (three out of four ewes) and tubal (six out of eight) insemination with fresh semen. Finally, it must be borne in mind that even after natural service under apparently ideal conditions early embryonic loss is usually within the range of 10-20 per cent^{14,15}.

Nevertheless the results indicate that early embryonic mortality is extremely high in the sheep after fertilization following uterine insemination with frozen semen. There may also be additional loss of the embryo at a later stage of development, as indicated by the difference between

non-return and lambing results^{6,16}.

We thank Mr I. D. Killeen for assistance and advice during experiment 1, Mr G. P. Walker for providing the sheep in experiment 2, and Miss A. Will and Mr T. Hunter for their assistance. The experiments received financial support from the Australian Wool Board.

Calcification in vitro of Human Aortic Tissue

CALCIFICATION in vitro of excised rat and rabbit acrta has been described previously1-5, but no comparable studies have been reported for the in vitro calcification of human aortic tissue. This communication reports the in vitro calcification of human aortic tissue using a procedure which measures the simultaneous deposition of calcium-45 and phosphorus-32. The mineral formed in the tissue was identified by X-ray diffraction analysis as hydroxyapatite.

Aortic tissue specimens were obtained at the autopsies of a 26 yr old male who died of cancer, a 37 yr old male who died of stab wounds and a 56 yr old female who died of cancer, to be referred to as tissues I, II and III, respectively. Tissue sections free of atherosclerosis were taken from the thoracic aorta. Calcification of the

tissues was induced in the following way. Fresh tissue was washed by mechanical shaking in physiological saline for 6 h to remove traces of blood. The wash solution was changed once after 3 h. After rinsing the washed tissue in triple distilled water, pieces (about 0.1 g) were cut, except for tissue II where 0.4 g pieces were cut, and a wet weight was taken. To ensure uniform penetration of the solution during calcification, incisions about 2-3 mm apart were made at least half-way through the tissue with a scalpel. The calcifying solution used for these experiments has been described before except that 100 mg of sodium ampicillin/l. calcifying solution was used instead of thymol. The quantities of calcium and phosphorus in the solution were adjusted to concentrations of 11 mg per cent and 5 mg per cent, respectively. The solution contained 20 μc . of calcium-45 and 20 µc. of phosphorus-32 as inorganic phosphate/l. of solution, and was freshly prepared for each experiment. The pH was 7.3. Control tubes containing only calcifying solution and stored in conditions identical to the calcification experiment remained stable for several weeks. The washed aortic tissue was placed in 28.8 ml. of calcifying solution in a tightly stoppered acid-washed glass tube. Calcification was allowed to proceed at 37° C. At specific time intervals of 2-123 h for tissue II, and 2-200 h for the other two specimens, tissue samples were removed and rinsed thoroughly in distilled water. Tissues were then ashed in a muffle furnace and the ash was dissolved in 2 ml. of 0.2 normal hydrochloric acid. An aliquot of the dissolved ash was pipetted into a naphthalene-PPO-POPOP-dioxane scintillation solution and calcium-45 and phosphorus-32 were counted simultaneously in an ambient temperature liquid scintillation counter. This method has previously yielded highly sensitive and reproducible results when applied to known calcification systems in vitro.

To determine the extent of calcium uptake resulting from true calcification it was necessary to measure (a) the amount of calcium bound in the absence of phosphate as well as (b) the exchange, if any, of residual tissue calcium with calcium-45 in the solution. The uptake of calcium by these means will be referred to as non-specific incorporation. These determinations were carried out by exposing aortic tissue samples to a solution containing all of the ingredients of the calcifying solution except for inorganic phosphate. All other conditions remained the same. The incorporation of calcium-45 from the solution into the tissue was followed with time. Tissue samples were treated as described here for the calcification pro-The samples were assayed as described for calcium-45. Similarly, the binding of labelled phosphate in the absence of calcium, also referred to as non-specific incorporation, was investigated in the same way as that described for calcium alone, using a solution containing all the ingredients for calcification except calcium. At various time intervals each tissue was removed, washed,

ashed and assayed as described before.

It is evident that there is some uptake of calcium-45 in the absence of phosphate (Fig. 1). The data shown in Fig. 1 indicate that some of the calcium taken up during calcification could result from non-specific incorporation. Also, some of the phosphorus-32 uptake could take place by some means other than calcification (Fig. 1). might be the result of a net incorporation of calcium (or phosphorus) unrelated to calcification or an exchange of the unlabelled element retained by the washed tissue with the labelled element from the solution. It is also possible that some combination of both mechanisms is responsible for the non-specific incorporation of calcium and phosphorus during calcification. These reservations must be considered in evaluating the results.

The first experiment made use of tissue II. From the results (Fig. I) it was evident that additional calcification could be achieved by extending the experimental period. The subsequent experiments involving tissues I and III were therefore extended to 200 h. Also, tissue weights

for the longer experiments were reduced from 0.4 g to 0.1 g in an attempt to reduce the amount of calcium and phosphorus being withdrawn from the solution. results of these experiments using solutions containing both calcium-45 and phosphorus-32 revealed that simultaneous deposition of calcium and phosphorus into aortic tissue increases for at least 123 h in the case of tissue II and at least 200 h for the other two specimens (Fig. 1), whereas the incorporation of either calcium or phosphorus alone showed little increase after 24 h. Because the uptake of either calcium or phosphorus alone shows no significant increase after 24 h in any of the specimens (Fig. 1), it can therefore be assumed that subsequent calcium and phosphorus uptake is chiefly, if not entirely, caused by calcification. Considerably more calcification took place in the experiments involving tissues I and III (Fig. 1). This was probably because of the time and weight changes previously described.

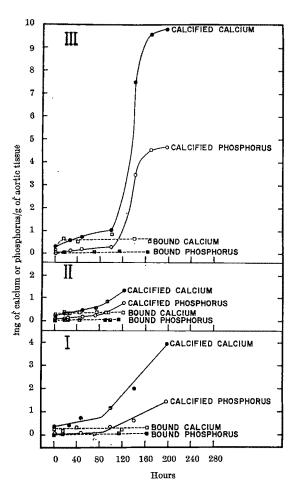

Fig. 1. The uptake of calcium () and phosphorus () during calcification is represented by the curves marked "calcified calcium" and "calcified phosphorus". The incorporation of calcium in the absence of phosphorus () and phosphorus in the absence of calcium () the represented by the curves marked "bound calcium" and "bound phosphorus". I, 26 yr old male; II, 37 yr old male; III, 56 yr old female.

A comparison of the rates of uptake of calcium-45 and phosphorus-32 during in vitro calcification of the three tissue samples as shown in Fig. 1 reveals some interesting similarities. The graphs for each tissue (Fig. 1) show a lag period followed by an inflexion point between 80 and 100 h and a subsequent increase in the slope of the curve. The patterns during the lag period are very similar and for tissues I and III are nearly superimposable up to the inflexion point. Apparently the weight difference between tissues I and II had no effect on the experiment until after the time of the inflexion point. The significance of the lag period described here is currently being investigated.

Aortic tissue samples from tissues I and III placed in calcifying solution for 200 h were subjected to X-ray diffraction procedures. The results showed a hydroxyapatite pattern, indicating that hydroxyapatite was formed during the calcification study. It is interesting that hydroxyapatite has also been found during calcification of aortic tissue in vivo? as well as in in vitro calcification studies with animal aortic tissues4. A Von Kossa stain done on the in vitro calcified aortic tissues was positive within the media as early as 72 h when cell nuclei were distinctly identifiable in haematoxylin and eosin.

Alteration by Pretreatment with Iproniazid and an Inactive Mescaline Analogue of a Behaviour Change induced by Mescaline

THERE have been several conflicting reports on the interaction of mescaline with monoamine oxidase inhibitors. Friedhoff and Goldstein¹, who gave 100 mg/kg iproniazid to rats, 24 h and 3 h before mescaline, found that this pretreatment had no effect on the gross behavioural changes induced by mescaline at 10, 25 and 100 mg/kg. The iproniazid pretreatment itself had produced a slight behavioural excitation at the time of administration of mescaline, and urine estimations of labelled mescaline showed that levels of the unmetabolized amine were considerably increased. In vitro experiments suggest that monoamine oxidase does not affect the metabolism of mescaline. Diamine oxidase (histamine oxidase) and a specific mescaline oxidase (found in rabbit liver), however, are probably involved in the oxidation. Iproniazid is not a specific monoamine oxidase inhibitor and is capable of inhibiting both histamine and mescaline oxidase, which would explain the increase in unmetabolized mescaline in urine. Goldwurm and Gualandri (personal communica-

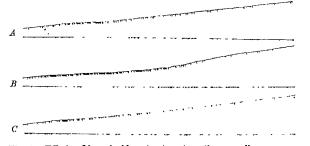

Fig. 1. Effects of ipronlazid pretreatment on the mescaline response. A and C, 17.5 mg/kg mescaline; B, 17.5 mg/kg mescaline pretreated with 50 mg/kg ipronlazid.

tion) found that pretreatment with iproniazid abolished the inhibitory action of mescaline on shuttle box avoidance in the rat. Steiner and Sulman² reported that iproniazid given before mescaline in the rabbit induced an anxiety reaction together with EEG changes.

We have examined the effect on rats of pretreatment with iproniazid. The subjects were three experimentally naive male hooded rats which were trained on a continuous discriminated avoidance schedule in a Skinner box until a stable level of performance was achieved. On this schedule an animal receives a shock of 0.5 see duration every 10 see unless it makes a bar press which postpones the shock for 30 sec. During the last 10 sec of this response-shock interval a discriminative stimulus light is turned on inside the experimental chamber. The stimulus light remains on until the animal makes a response which initiates a new cycle.

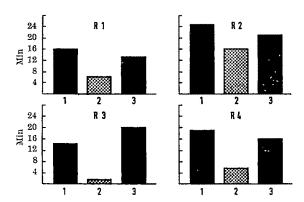

Fig. 2. Duration of inhibitory period for four experimental animals subjected to the three drug conditions. 1 and 3, 12·5 mg/kg mescaline; 2, 12·5 mg/kg mescaline pretreated with 25 mg/kg 2,4,5-trimethoxy-phenylethylamine.

Throughout the experiment, each subject was tested at the same time every day for 2.75 h. The experimental session can be sub-divided into a 15 min "warm-up" period, a 30 min pre-injection or control period and a 2 h test period. Each subject served as its own control and was injected with a control physiological saline solution on the days before and after drug administration. With the exception of the days before the treatment started, all drugs were given after the pre-injection period and the subject was immediately placed in the Skinner box for the 2 h test period. A pilot study revealed that 100 mg/kg of iproniazid had some behavioural effects on the avoidance schedule so the pretreatment dosage was halved to 50 mg/kg. At this dose there was no behavioural effect at any time after injection. Initially, the response of each animal to 17.5 mg/kg mescaline was determined (Fig. 1A). Previous experiments had shown that this dosage would have a noticeable, but not extreme, effect on behaviour. Fourteen days later each animal received 50 mg/kg of iproniazid (intraperitoneally) 3 h before the administration of 17.5 mg/kg of mescaline. As a further control 17.5 mg/kg of mescaline was given again after 4 weeks. Fig. 1B shows the influence of iproniazid pretreatment on the action of this dose of mescaline. There is a marked increase in the effect of the drug. The entire procedure was repeated for each animal and the increase in the effect of mescaline was verified.

This finding does not support the theory that mescaline acts through a metabolite but suggests that the free amine level is the critical factor. An alternative hypothesis is that the increased levels of other monoamines, after iproniazid pretreatment, in some way facilitate the hallucinogenic activity of mescaline. A number of experiments are suggested by the latter hypothesis. If endogenous amine levels are involved, then pretreatment with amine depleters such as reserpine or tetrabenazine

should decrease hallucinogenic activity and specific monoamine oxidase inhibitors (possibly N-octanol) should The reversal of the enhance hallucinogenic activity. mescaline effect by pretreatment with tetrabenazine would avoid any interpretation of the results as the summated effects of two independent processes. because both mescaline and tetrabenazine block the conditioned avoidance response, then any reversal of the mescaline effect would be in the opposite direction to both manipulations. Furthermore, because pharmacological agents are available which selectively interfere with the synthesis of particular amines, then it might be possible to delineate further the precise action of mescaline.

A second pretreatment experiment was undertaken in order to throw some light on the specificity of the mescaline molecule. Four experimentally naive male hooded rats were kept on a restricted 23·5 h water deprivation schedule. All subjects were trained to press a lever in a Skinner box for access for 1 sec to water reinforcement. After preliminary training, reinforcements were only delivered when a response occurred at least 15 sec after the previous one (DRL 15). When the animals had reached a stable level of performance, each subject was initially treated with 12·5 mg/kg mescaline. The effect of the drug is to cause a period of complete suppression of lever pressing. It has already been shown that the duration of the inhibitory period is a good index of drug dose.

Fourteen days later these animals were given 25 mg/kg of 2,4,5-trimethoxyphenylethylamine (2,4,5-TMPE) followed after 15 min by 12·5 mg/kg of 3,4,5-trimethoxyphenylethylamine (mescaline). The pretreatment compound is inactive at this dosage³. After a further 14 days, 12·5 mg/kg of mescaline was again administered. The duration of the inhibitory period was measured for all three conditions (Fig. 2). It is clear that the effect of pretreatment was to decrease the mescaline response.

The antagonism between these two closely related compounds would suggest that 2,4,5-TMPE is capable of occupying the mescaline receptor site or blocking related transport mechanisms, though itself having no central effect. In this case a systematic study of the other fifteen inactive ring methoxylated phenylethylamines in this situation may yield data as to properties of the receptor site involved.

Weissenberg Effect as an End-point in Coagulation Studies

During a recent investigation of the viscosity changes which occur when thrombin is added continuously to fibrinogen, the substrate solution suddenly and rapidly climbed the shaft of a motor driven paddle at about the conventional coagulation point. This phenomenon is familiar to investigators of artificial high polymers as the Weissenberg effect¹⁻³, which is usually observed where the macromolecules or other structures form a network of temporary entanglements or permanent cross-linkages.

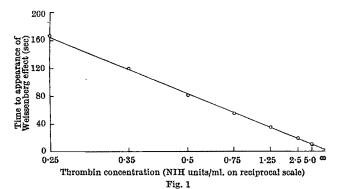

To our knowledge, the effect has not been noted in the case of fibrin. It occurred to us to investigate whether the appearance of the effect might provide a useful end-point in coagulation studies.

We used a commercial standardized concentrate of bovine thrombin (Parke, Davis and Co., thrombin "Topical") diluted with normal saline, and a freeze-dried preparation of human fibrinogen (85 per cent "clottable" protein) separated from time-expired plasma and made available to us by the Lister Institute. The fibrinogen preparation was dissolved in distilled water to give the concentrations: "clottable" protein 9.0 mg/ml.; "non-clottable" protein 1.5 mg/ml.; sodium chloride 17.0 mg/ml.; trisodium citrate 7.4 mg/ml. This solution was filtered by means of a P_1 sintered glass filter before use.

A volume of 0.9 ml. of the substrate solution was placed in a 16 \times 120 mm test tube immersed in a water bath at a temperature of $37^{\circ} \pm 0.05^{\circ}$ C. A stirrer, made of a solid glass rod 3.5 mm in diameter with a 10 mm long T-piece, was placed in position with the cross-piece well immersed and the variable speed stirrer motor was started. The thrombin solution in a volume of 0.1 ml. in a syringe was immersed in the bath for a sufficient time to equilibrate its temperature and then added to the substrate solution in a single amount. The time to the appearance of the Weissenberg effect was measured with a stop watch. Fig. 1 gives the results obtained at a stirring speed of 2.8 r.p.s., for a range of thrombin concentrations in the final coagulating solutions between 0.25 and 5.0 NIH units/ml. The time to the appearance of the Weissenberg effect, when plotted against the thrombin concentration on a reciprocal scale, gives an excellent linear relationship: the deviations on the time axis from the best straight line are, in this case, within the limits ± 1 per cent ± 1 sec. (More generally the deviations from the best straight line were within the limits ± 3 per cent ± 1 sec.) The linear relationship between the concentration of thrombin and clotting time is well known4.

With the geometry and quantities described, we found that below the speed of stirring of 2.8 r.p.s., the Weissenberg effect was not reliable and occasionally failed for the highest thrombin concentrations within our experimental range; we presume that the shear rate in the neighbourhood of the stirrer was insufficient to develop an elastic force which could overcome the gravitational force before the gel was completely firm.

Above about 5.4 r.p.s., the effect was lost at the lowest concentrations of thrombin. When the volume of the solution was doubled in a 22×150 mm test tube, the upper limit was increased to about 9 r.p.s. With 20 ml. of substrate contained in a beaker with a slightly larger stirrer (5.5 mm diameter rod, 21 mm T-piece), it was possible to observe the Weissenberg effect throughout the whole experimental range up to a stirring speed of 16 r.p.s., at which point the stirrer started to draw bubbles of air into the solution. Presumably, in the narrower vessels, at the upper limits, a sufficiently high shear rate was

being developed at the stirrer to inhibit the formation of the molecular network.

In general, the faster the stirring rate, the sharper was the Weissenberg effect observed. For a fixed concentration of thrombin, the time to the appearance of the Weissenberg effect depended on the stirring rate: in the case of the large volume of substrate in a beaker with a thrombin concentration of 1.25 U/ml. of substrate, the time decreased from about 43 to 37 sec as the speed of the stirrer was increased from 2.4 to 16 r.p.s. The decrease of coagulation time with an increase in shear rate has already been noted^{5,6}. For determining curves, such as that in Fig. 1, we have used a stirring speed just above the lower limit.

The most commonly used method for determining the coagulation time is to note the point at which flow is no longer obtained when the container is tilted⁴. Another popular method depends on noting the time at which the optical density changes by a significant amount⁴. Other optical and mechanical methods have been described⁷⁻¹⁰. The observation of the Weissenberg effect provides a more objective and precise end-point than the first method and may be somewhat simpler than the others.

We thank Dr Maycock of the Lister Institute for providing us with the fibrinogen. This investigation was supported by the US Public Health Service and the British Heart Foundation.

PSYCHOLOGY

Conditions for Successful Transfer Effects

LEARNED behaviour is reported to be transmitted by injecting into untrained animals fractions¹⁻⁴ or homogenates⁵, containing RNA, from the cerebral hemispheres of trained rats. Others⁶⁻⁸ have been unable to confirm these positive transfer effects. The transfer problem is very important for the understanding of memory and learning, and we have carried out a series of experiments with rats to investigate certain preliminary conditions which may be important in the positive or negative results which have been reported.

A defensive motor response (jumping up to a shelf) was conditioned by pairing an acoustic stimulus (bell) with an electric shock applied through the floor grid of the training box, 12 cm below the shelf. The experimental session consisted of four successive trials with intertrial intervals of 1 min. The unconditional stimulus (electric shock) was delivered with a delay of 5 sec after the conditioned stimulus (bell) unless the rat jumped onto the shelf. Groups of trained animals which performed completely (100 per cent) the conditional response served

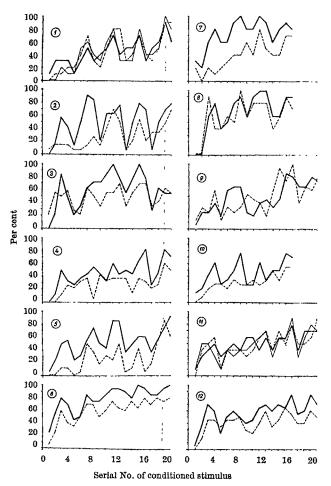

Fig. 1. Conditioned motor response of the groups of recipient rats injected intraperitoneally by brain extracts of trained (heavy lines) and untrained (dotted lines) donors. Diagrams 1 to 12 represent the chronological sequence of the experimental series. Abscissa: seriel number of conditioned stimulus. Ordinate: percentage of the recipient animals performing the conditioned response (jumping on to the shelf). In series 1 and 11 two groups of recipients were treated with extracts from trained rats, and one with extracts from untrained rats.

as donors. In all experiments, the phenol extraction procedure already described^{3,4} was used. Each recipient was given intraperitoneally 1 ml. of a solution containing total brain RNA extract from one donor (1·6-1·8 mg/ml. of RNA, determined spectrophotometrically).

Male Wistar rats (362) served as donors. Three different trained donor groups were used: (a) series 10 and 11 with a "low" ("short term") conditioning (five sessions in 3 days); (b) series 2, 3, 4, 5, 6, 7 and 9 with a "medium" ("normal term") conditioning (twelve sessions in 10 days); and (c) series 1 and 8 with a "high" ("long term") conditioning (twenty-four sessions in 20 days). The control donor groups consisted of untrained animals.

Another 362 male Wistar rats were used as recipients. The recipients were divided. before injection, into groups; (a) some groups were completely habituated to the conditioned stimulus and additionally trained to jump up to the shelf (series I and 7); (b) some groups were trained only to jump up to the shelf after electric shock, but not habituated to the conditioned stimulus (series 2.

3, 5, 6, 7, 9, 10, 11 and 12). Series 3 and 6 were young animals, 4 months old. Finally, (c) a third recipient group was trained to neither the conditioned nor the unconditioned stimulus. After intraperitoneal injection the recipient groups were tested in the same way with the trained donors, that is four successive trials in each session, 4, 8, 12, 28, 52, 76, 100 and so on hours after the injection of the brain extract. The experimental and control groups were conditioned and tested completely "blind", that is the experimenter did not know what previous treatment the animals had received.

The level of significance of the conditioned performance of the recipient groups injected with extracts of brain of trained donors, when compared with the recipient groups injected with brain extracts from untrained donors, was calculated by means of the Wilcoxon test, on the basis of the results of the first three sessions after injection.

A general trend is revealed in Fig. 1, which shows that injectees which received extracts of trained donors performed better than recipients of control brain extracts. The difference between the trained and the control group is most striking, however, in series 2, 4, 5, 6, 7, 10 and 12. This is explained by the following conditions (summarized in Table 1). (a) If the donors are poorly trained, the transfer effect is not excluded (series 10), but occurs with a lower level of significance (P < 0.05). In series 11 no transfer effect was observable. (b) If the donors are "over-conditioned". no significant transfer effect can be observed (series 1 and (c) If the recipients are habituated only to the unconditioned stimulus before injection, or if they receive no preliminary training, the memory transfer takes place. It does not occur, however, if they are habituated to the conditioned stimulus before the administration of the brain extract. (d) The young recipients first habituated to the unconditioned stimulus are probably less suitable for transfer studies than the mature animals (series 3, unsuccessful; series 6, successful).

Thus it seems that in our experimental conditions the optimal transfer effect occurs when donors are trained for 10 days (twelve experimental sessions) and when adult recipients are not habituated to the conditioned stimulus (series 2, 5, 7 and 12).

Our findings do not, of course, indicate whether they concern the transfer of some specific memory mechanism or simply of a certain kind of excitatory state. Furthermore, they are not directly relevant to the detailed mechanism, or to the nature of the chemical agent transmitted. These results may be valuable in filling the gap

between conflicting data¹⁻⁸ and in stimulating further investigation.

GENERAL

Entropy and Evolution

CAMPBELL'S expressed aim1 is "to describe the entropy pump whereby the species of living matter not only prevent a drop into a position of greater positive entropy at each generation, but may in fact acquire more negentropy as their reproduction continues". This is attempted by recourse to the example of a codfish laying a million eggs the entropy content of whose genomes shows a normal distribution about a mean value in accordance with the second law of thermodynamics. On one tail of this distribution curve will be a small percentage of eggs with an entropy content equal to or less than that of the parents. There follows the crucial sentence: "These There follows the crucial sentence: remarkable ones are most likely to grow up and repeat the reproductive process". What follows in Campbell's communication is unexceptionable provided that this sentence is true. But what is the evidence that those eggs which are "most likely to grow and repeat the reproductive process" are those whose genomes have a lower entropy content than those of the parents? It is at this point that the author merely evades one of the most important questions at issue in the earlier correspondence²⁻⁴. The genome may be regarded as a series of DNA molecules functioning as templates. The thermodynamic entropy content of these molecules is a function of the arrangement of the atoms, conventionally expressed as $k.\log D$ where k is the Boltzmann constant and D is a measure of the atomic disorder. A single alteration in the relative positions of adjacent nucleotide bases could convert a crucial part of the genome code to nonsense so that its capacity to support development was lost, but this could occur without an increase, indeed even with a decrease, in the thermodynamic entropy content of the genome molecules. Stated in a more general way, this is the problem of the relationship between the amount of developmentally meaningful organization in the genome (we will call this the information content) and its entropy content. There are two problems here: first, the definition and quantization of the information content of the genome and, second, the nature of its relationship to the thermodynamic entropy content. One avenue of enquiry which offers hope in this situation would seem to be the information theory analogy.

Szilard⁶ pointed to the formal similarity between the equations defining information

$$H = -\sum_{i=1}^{i=n} \text{pi log. pi}$$

(where $0 \le pi \le 1$, $\sum_{i=1}^{n} pi = 1$ and pi is the relative probability of the *i*th symbol generated by a source), and entropy defined in statistical terms as

$$S = -i\sum_{i=1}^{i=n} pi \log_{i} pi$$

(where Σ_{i}^{n} pi = 1 and pi is in this case the probability of an idealized physical system being in the state i of n possible equivalent states).

The work of Shannon⁷ and Brillouin⁸ showed the fundamental relationship between information and entropy defined in these terms. It is the unwarranted extrapolation of this relationship to biological systems which leads to erroneous conclusions, although the warning was admirably given by Brillouin himself*: "The present theory of information completely ignores the value (or meaning) of the information handled, transmitted or processed. This point has been very carefully emphasized throughout this book. Many other writers seem not to have realized the importance of this restriction, and many misunderstandings about the possibilities of the present theory resulted from this situation". This is the biological problem because, as I have said, different arrangements of equal members of nucleotides may have the same thermodynamic entropy but a different value in the context of the development and viability of the organism. It may be that, as Lwoff⁵ has supposed, this functional order cannot be measured in terms of entropy units and is meaningless from a purely thermodynamical point of view. But this may be an over-pessimistic view. For example, one possibility which seems worth exploring arises from possible analogy with the work of Carnap and Bar-Hillel¹⁰, who have applied techniques of symbolic logic to define the information content of a sentence. Now if for a very simple organism such as Mycoplasma, one came to know the complete nucleotide sequences and the limits of their physical variation within each operon consistent with successful replication and development, and the essential sequence of operon functions necessary for development, it might be possible to define the information content of the organism in terms of the number of base sequences commensurate with reproduction and development. From this it is conceivable that one might obtain a "content measure" bearing at least a qualitative similarity to the information equation of statistical thermodynamics. If this were achieved one would then in effect be saying something in thermodynamic terms about what marked off the living from the non-living. This may seem a long shot, and indeed ignores the whole question of essential extra-genomic factors11, but in any event until this or other possible approaches to the problem are explored we cannot with any confidence pronounce on either the direction or the magnitude of the thermodynamic entropy changes involved in the acquisition of the "fuller informational systems" which are the products of evolution. This being so, it would seem premature to speak of an 'entropy pump''.

BOOK REVIEWS

DALTONIAN REVOLUTION

Atoms and Elements

A Study of Theories of Matter in England in the Nineteenth Century. By David M. Knight. (The History of Scientific Ideas.) Pp. 167. (London: Hutchinson and Co. (Publishers), Ltd., 1967.) 30s. net.

It is customary to regard nineteenth century chemistry as proceeding smoothly in the wake of a chemical revolution initiated by Lavoisier; but, as this book shows, there was another revolution stemming from Dalton's atomic theory. It is not the case, of course, that Dalton's theory was universally accepted; it was not, even by English chemists. But the importance of Dalton's theory and its inclusion of the very useful and helpful theory of definite proportions made chemists necessarily more sensitive to the problem of the nature of matter, and caused physicists to realize that theories of matter must meet chemical as well as physical tests. That physicists like Kelvin were forced to take chemical problems into consideration when attempting to devise a new theory of matter is an indication both of the power of Dalton's work and of the growing maturity of chemistry.

The conventional view of the history of atomic theories in the nineteenth century has been that the Daltonian atom was unacceptable to physicists because of its "billiard ball" characteristics. As Dr Knight here shows, the real snag about the Daltonian atom was metaphysical, not physical: chemists and physicists alike generally preferred the view that matter is homogeneous to Dalton's view that the atom of each element is physically and therefore chemically distinct. They were also truer Newtonians than Dalton, and conscious of the existence of forces. For all these reasons, as recent work on the history of science has shown, English physicists and chemists of the nineteenth century found the atomic theory of Boscovich peculiarly satisfying. The attempts of Boscovich himself to apply his theory of point forces (endowed with inertia) to chemistry had not been very successful, but his Theoria naturalis philosophiae was too early (it was published at Venice in 1763) for his chemical knowledge to have anything to contribute to the nineteenth century; indeed his applications of his theory to physics were not noticeably more helpful. But the theory itself was wonderfully versatile and appealed particularly to English natural philosophers. (On the whole, continental scientists were more pragmatic.) Expounded in the supplement to the third edition of the Encyclopaedia Britannica (1803), discussed in early lectures at the Royal Institution by Thomas Garnett (1801), Boscovich's theory was adopted successively by Davy and Faraday and remained a dominant feature of English scientific thought in the nineteenth century, being used at the end of the century by J. J. Thomson.

In spite of its title, this book is mainly about the atom in chemistry; the author has not discussed the relation of theories of matter to the development of such physical problems as the kinetic theory of gases. It is also mainly concerned with the earlier half of the century. The sixth chapter does deal with the curious "debates" between officers of the Chemical Society in the late 1860s, and there is an epilogue on the next two decades, but these are specialized and not so easy to follow as the earlier chapters. Unlike the earlier chapters, these later ones presuppose considerable knowledge of the history of

chemistry in the period—of the development of the periodic table, of the long, tangled and slow growth of an understanding of organic compounds, and of the acceptance of the theory of valency. Two of the leading English protagonists in the development of the concepts of valency and organic structure, Alexander Williamson and William Odling, were active in these debates; the problems there raised have been more fully and therefore more lucidly developed in the accounts already published by the author in collaboration with W. H. Brock.

It is a fascinating subject for chemistry and physics alike, and one little studied so far. This book makes an admirable introduction to a subject worthy of much further study.

MARIE BOAS HALL

MATHEMATICAL LOGIC

Mathematical Logic

By Stephen Cole Kleene. Pp. xiii + 398. (New York and London: John Wiley and Sons, Inc., 1967.) 85s.

This book for undergraduate study is written by the author of a famous postgraduate text Introduction to Metamathematics written nearly twenty years ago. Like the more advanced work the present volume is characterized by its comprehensiveness and thorough treatment. Sentence and predicate logic are both presented in a variety of ways, from model theory to several versions of proof theory including axiomatic proof theory, natural inference and (in the last chapter) Gentzen's sequent calculus. The account of the difficult subject of substitution in predicate logic is particularly successful, but I do not consider the treatment of sentence formation which allows collision of variables and vacuous quantification suitable for a first course in logic. The simplicity gained in the definition must be paid for at too high a price in the interpretation of sentences like VxExPx in the model theory; I think a clearer distinction and separation between free and bound variables (and not just free and bound occurrences) is desirable for beginners in predicate logic even if this requires a definition of sentence by level of complexity.

As one would expect from one of the pioneers in general recursive function theory, the chapter on computability and decidability is extremely good and contains many references to recent work; for instance, on degrees of unsolvability and the arithmetical hierarchies (which the author initiated).

Completeness of predicate logic is established by means of Gentzen's sequent calculus and a proof of the equivalence of the axiomatic and the sequent formulations; the idea behind the completeness proof is to set up a systematic method of search which for any predicate sentence F leads either to a counter example to F if there is one or to a closing of all avenues to a counter example when F is valid. The equivalence of the axiomatic and sequent formulations is also exploited to give a simple proof of Craig's interpolation theorem for predicate calculus with equality which says that if $E \supset F$ is provable then there is a sentence I the parameters of which are common to E and F such that $E \supset I$ and $I \supset F$ are both provable.

R. L. GOODSTEIN

ELECTRON DIFFRACTION METHOD

Electron-Diffraction Analysis of Clay Mineral Structures By B. B. Zvyagin. Revised edition. Translated from the Russian by Simon Lyse. (Monographs in Geoscience.) Pp. xvi+364. (New York: Plenum Press, 1967.) \$19.50. For crystal structural studies, the method of singlecrystal X-ray diffraction is generally the most successful,

but because of the fine grained nature of clays, only powder

X-ray data can as a rule be obtained from these materials, with consequent loss of information. The usefulness of the X-ray powder method is, moreover, further limited for clays because of the difficulty of preparing a truly randomly oriented powder specimen from aggregates of platy particles. It has long been appreciated, therefore, that the method of diffraction from a single crystal using a fine beam of electrons would be a useful one for the study of the structures of clay minerals, but this also is not without difficulties. The first is again the problem of preferred orientation, the platy clay particles tending to lie parallel to the supporting substrate, and therefore limiting the amount of diffraction data that can be recorded. The second difficulty is the interpretation of the observed electron diffraction intensities, because these are considerably affected by dynamical interaction between the diffracted and transmitted beams and by other factors which are not easily estimated quantitatively. It is interesting to compare the rather different ways in which these two obstacles have been regarded and dealt with in the Soviet Union (illustrated by Zvyagin's book) as compared with the approach by most other workers.

The Russian school, exemplified by Pinsker, Vainstein, Zvyagin and co-workers, have overcome specimen orientation difficulties by using specially designed electron diffraction cameras. These have allowed the tilting of the specimen stage to quite high angles, and have led to the use of the "oblique texture" method which gives a reasonable coverage of the diffraction data in reciprocal space. Most workers elsewhere have tended to make do with their electron microscopes for electron diffraction work, and the requirement of high resolution microscopy has (until very recently) militated against the provision of high-tilt specimen stage facilities. Of course, the electron diffraction camera user cannot see an image of the crystal which is giving the electron diffraction pattern, but in the study of particular specimens of clay minerals which are known to be homogeneous this is not a great disadvantage.

The difficulties concerning electron diffraction intensities have daunted many, but the Russian school has pressed on regardless. There is no doubt that, except in very favourable circumstances, a highly accurate structure determination cannot be achieved using electron diffraction intensities, but crystallographers know well that even rough relative intensities can yield a close approximation to the correct atomic co-ordinates of a structure. It has thus been possible for Zvyagin and others to obtain useful structural information about clay minerals using electron diffraction which could not be determined in any other way.

The greater part of this book is concerned with the electron diffraction method and results, but a useful additional topic is dealt with in the first chapter, which describes the structures, polymorphs and polytypes of layered silicates. Here Zvyagin's systematic approach and specially devised notation are of great interest. The second chapter describes the electron diffraction apparatus, while the third and fourth chapters treat the theory of electron diffraction analysis in general, and in particular the "oblique texture" method applied to layered silicates. The fifth chapter gives examples of structure determinations of clay minerals which have been effected by the foregoing methods: these include kaolinite, celadonite, muscovite, phlogopite, nacrite, sepiolite and palygorskite.

For the reasons discussed here, relatively little mention is made of combined electron microscopy and diffraction. With the recent development of high resolution electron microscopes with facilities for high angles of specimen tilt, the researcher can have the best of both worlds. Furthermore, dark-field imaging, using selected diffraction spectra, is proving important for the study of short range detail rather than the long range average structural features examined by X-ray diffraction. Thus the advantages of electron diffraction camera work are far fewer now than

they were when this book was written in Russian in 1964. Others may now, using electron microscopes or cameras, take advantage of the methods and treatments set out so clearly by Zvyagin.

The author has taken the opportunity, on the occasion of the book's translation from the Russian, to make some revisions, and to add new material concerning the serpentine minerals, hallowsite, chlorites and disordered micas. The translation and technical reproduction of the book are both of a high standard, except in the case of the relatively few electron micrographs shown, which are less clear than the electron diffraction patterns.

This book can be read with profit by all those interested in the crystal structures of clay minerals or in the techniques of electron diffraction.

J. Zussman

NON-FERROUS HEAVY METALS

The Technology of Heavy Non-Ferrous Metals and Alloys

Copper, Nickel, Zinc, Tin, Lead. By J. H. Cairns and P. T. Gilbert. (Newnes International Monographs on Materials Science and Technology.) Pp. viii+319+2 plates. (London: George Newnes, Ltd., 1967.) 70s. net.

This book sets out to emphasize practical applications rather than scientific aspects, and thereby defines its usefulness to metallurgists, engineers and designers. It achieves these objectives very well, particularly in the excellent summary of mechanical working processes and the five chapters on applications.

It is least successful when summarizing the physical and mechanical properties, although, in fairness, the fly-leaf declares that this section is "not intended to be as detailed as the standard metallurgical textbooks". Typical of the surprising statements made here is that specific heat "increases slightly with rise of temperature", followed by a general approximation of "5 per cent per 100° C", which is hardly slight. Nowhere is there any incorrect statement, but the appeal is more to the old fashioned concepts of many engineers and designers than to the new approach of the Council of Engineering Institutions.

No mention of powder metallurgy processes or products is made, except for sintered bronze bearings, and in the section on welding, the friction process does not appear. In assessing the appropriate properties for bearings, the importance of fatigue strength is omitted. Unusual entries in the index include "beer" and "whisky", for production of which considerable quantities of copper and nickel are employed. One excellent feature of the index is a separate list of those maddening specification numbers for metallic materials and components made from them. Few books in this field are produced outside the publications of the metal development associations, and so the authors are to be congratulated on this volume.

C. R. TOTTLE

NO VITALISM FOR CRICK

Of Molecules and Men

By Francis Crick. Pp. xv+99. (Seattle and London: University of Washington Press, 1966.) 30s. net.

For his John Danz Lectures, given at the University of Washington, Francis Crick took a title very appropriate for the field in which his work is so well known; but it was, perhaps, rather a quirk to choose to develop his theme in terms of an attack on vitalism. Is this not flogging a dead horse? Crick is at pains to point out that the horse is still kicking, if faintly. "And so," he writes, "finally, we come to the question, 'Is vitalism dead?'. It

seems to me that, reluctantly, we must answer, 'No'. While there are intelligent people alive who sincerely believe in vitalistic ideas, even though they are fully acquainted with the scientific knowledge on the subject, we must conclude that vitalism is still alive. There remains the question how we can disprove it . . .".

The trouble is to define just what we mean by "vitalism".

Crick writes at one point (page 26), "We have seen that it means that there must be something else in a biological system which cannot be included under the heading of physics and chemistry". But what can, or cannot, be included under that heading? Crick often writes as though physics and chemistry are a complete systempresumably "classical", because quantum considerations are scarcely mentioned. "It is my argument that our present general knowledge of physics and chemistry is sufficient to act as an exceedingly solid foundation, though, let me add, much of the detailed chemistry is incomplete and needs much further study". One must ask, is a quark included? And if biologists should find it necessary to postulate an entity as odd as a quark, would that be vitalistic or not? The controversy about vitalism arose at a time when physicists thought they knew what the fundamental physical entities consist of. It takes a new form, which is much harder to define, at a time like the present when no physicist would make such a claim—when indeed it is becoming more plausible to suggest that there is no such thing as a truly fundamental physical entity, but that the universe is an open system, providing an infinite perspective for deeper and deeper study, probably in both directions, into the infinitely small sub-nuclear particles and the infinitely large cosmological systems.

In my opinion, the first step in any worthwhile discussion of vitalism is to make a distinction between what may be called the objective and subjective varieties of it1. The former holds that there is something not physically explicable about the observable behaviour of living systems; the latter makes the point that the difficulty arises in connexion with functions such as consciousness or awareness, which we can experience within ourselves but which we cannot actually observe in any other biological entities, although we may postulate their existence there. These are really two quite different points, although often confused, both by Crick and by many of the authors

he accuses of vitalism.

Elsasser, who is one of Crick's targets, is perhaps an objective vitalist. Crick has little difficulty in disposing of his arguments in the form they were first put forward² in which Elsasser was deceived by the ballyhoo about information theory to argue that there is some quite mysterious increase in information content between the egg and the adult. As Crick correctly points out, we have at present no possible way of estimating how much "information" is required to build up an organ like a hand, so Elsasser's dilemma does not arise. In point of fact, of course, the basis for the development of an organ is not properly called "information" at all; it consists of "instructions" or "algorithms" (that is, genes that make proteins that do something, to put it very crudely). In a recent book, however, Elsasser³ has put his point in a different form which cannot be so easily dismissed. Again putting it shortly and crudely, he claims that biological systems involve interactions between elementary units (genes, for example) numbered in 105's at least; the number of interactions will rise into the realm of "immense numbers", where end-states become uncomputable, and, he claims, uncomputable in principle. This is a difficulty very analogous to that known in physics as the problem of quantum measurement, or the translation from a quantum system to a classical system. I think there probably is a real difficulty here, although I am not a good enough physicist to understand it fully; but there seems little reason to feel that the biologists are much worse off than the physicists, who have not solved their own problem yet to everyone's satisfac-

As Crick points out (page 26), biology has available a category of explanation to deal with complex systems which is not used in the physical sciences, namely. natural selection. I agree with him that this principle might operate, in simple forms, in non-living systems, but in the biological world it has been developed into an exceedingly subtle and powerful process for producing highly organized entities. In my opinion, the concept has been somewhat debased in current biology by premature mathematization in terms of rather simple algebra. In consequence, it tends to be called in as a deus ex machina. all-powerful in principle but yielding little understanding in detail. It can certainly help us meet some of the arguments of the vitalists, but we still need to think a good deal harder about precisely how it operates.

Most of those Crick accuses of vitalism are more or less influenced by the subjective experience of consciousness. The problems presented by the central nervous system are, I think, of two quite different kinds. Consider running downstairs to answer the telephone; you may be conscious of nothing but "will the message be yes or no"; neurones are, of course, firing like mad, and fantastic feats of computation being performed as you go from step to step and around the corner. An objective vitalist would argue that these unconscious processes are for some reason, perhaps Elsasser's complexity point, not physically explicable. The subjective vitalist's point is that you may be consciously aware of something; possibly something complex, like planning your answer, or possibly something very simple, such as a single colour in which the wall is painted; and what is inexplicable, he maintains, is this awareness. This is quite independent of the complexity of the content of consciousness. In fact, because one can perform extremely complicated actions unconsciously, and can also be aware of extremely simple things, it is not plausible to argue that complexity has anything to do with the situation, one way or another.

The thesis that consciousness or awareness belongs to a different logical realm from that inhabited by present day science, which deals with observable behaviour. is, I think, irrefutable. This is not the place to discuss the philosophical problem of whether science could be modified so as to penetrate this realm as well. The point to make here is that Crick is quite right to insist, as he does (page 24), on the reciprocal of this; namely, that it is illegitimate to use the existence of consciousness as an argument for the necessity of non-physical laws to account for the behaviour of biological systems, as Wigner did. But it is, surely, a return to another of Crick's quirks to find the discussion of such matters leading to the old arguments—rather fully summarized in Needham's History of Embryology-of the time at which the soul enters the human foetus (page 85).

BIRDS, BEES AND BACTERIA

Penguin Science Survey 1967

The Biology of Sex. Edited by Anthony Allison. Pp. 288+17 plates. (Harmondsworth, Middx.: Penguin Books, Ltd., 1967.) 12s. 6d.

What is sex? Many a treatise on the biology of sex has foundered in an attempt to define its subject, and because the Penguin Science Survey for 1967 has no less than sixteen contributors, one should, perhaps, not expect a unified approach. A glance at the table of contents will show that one's caution is justified.

This is an age of mini-fashions and biologists are nothing if not fashionable. The first chapter is on "Sex in Bacteria" by William Hayes and this is followed by "Sexual Reproduction in Protozoa" by G. H. Beale. From there we graduate to "Sex in Plants" by Kenneth Lewis and Bernard John, followed by "Sex Determination in Insects" by John Anderson. At last we are ready for "Sex Determination in Mammals" by R. A. Beatty, "The X Chromosomes and Gene Action in Mammals" by Mary Lyon and "The Sex-Ratio in Man" by A. S. Parkes. Now come four chapters on insects with varying connexions with sex: "The Chemical Basis of Courtship in the Insect World" by R. K. Callow, "Sound and Vision in the Sex Life of Insects" by H. Hurst, "The Rabbit Flea and Hormones" by Miriam Rothschild and "Control of Insects by Sexual Sterilization" by G. B. White. Then, after a chapter on "Sexual Behaviour in Mammals" by Paul Leyhausen, biology is left behind and we have "Sex in Psychoanalysis" by Irving Bieber, "Anthropology and the Sex Problem" by D. F. Pocock and "Sexual Deviation" by T. C. N. Gibbens.

To start at the beginning, Professor Hayes writes that "If we look for a common denominator of . . . sex . . It is an alternating cycle in which two haploid parental cells . . . pool their genetic material in a single diploid cell or zygote; this zygote ... subsequently segregates haploid progeny". True, but a common denominator is obviously less than the whole. Nevertheless, all the biological authors including the editor, who writes the introduction, seem to equate sex with sexual reproduction or basically the fusion of haploid nuclei followed by meiosis, the function of which is to provide new combinations of genes for natural selection to work on. Nobody seems to have thought it worth mentioning that, for instance, in man the volume of the egg cell is many thousand times that of the sperm. Not only is the large egg cell responsible for the complex development of the early embryo but the production of such diverse reproductive cells is associated with far-reaching physical and behavioural differences in the organisms which make them. Thus, sex is not just a mechanism to promote outbreeding, for which it is not necessarily very efficient and may indeed be downright useless, as pointed out by Professor Beale in connexion with autogamous protozoa. Self-fertilizing plants come into the same category. In its fully developed form, the sexual condition provides for the formation of highly complex organisms, which are themselves divided into two classes. It is surely the physical differences between males and females which provide the link between the biology of sex and its psychological and anthropological aspects. As it is, the different chapters are quite unconnected and, indeed, the word "sex" has entirely different meanings in different parts of the book.

Granted, then, that there is no unifying thread and that, moreover, the biology of sex has got rather a rough deal, the individual contributions are certainly worth reading. To mention only a few, the chapters on bacteria and protozoa are both models of clear exposition and, though their connexion with sex may be slight, this does not in any way detract from their interest. Nobody thinks any the less of prehistoric caves because they do not teach us much about architecture. "Sex Determination in Insects" is a useful summary of the classical cytogenetic facts of sex determination and also contains more recent work on experimental sex reversal. This chapter, however, is not always easy to follow, partly because the author uses such terms as "endomitosis" and "heterochromatization" without a word of explanation and also because of his attempt to explain the mode of action of sex chromo-This topic is still an unsolved problem and it would have been less painful to say so. The same problem crops up also in "Sex Determination in Mammals", which otherwise is a workmanlike account of the chromosomal and embryological bases of mammalian sex dimorphism. "The Sex-Ratio in Man" is a topic of great general

interest but one on which scientific data tend to be inadequate, and Professor Parkes is not afraid to say so. The subject of "The X Chromosomes and Gene Action in Mammals" would seem hardly ready for popular consumption but Dr Lyon has solved this problem by giving only one side of the story. The history of biology has many examples in which facts have eventually accommodated themselves to theory and time will show how far this will happen to the Lyon hypothesis.

One of the most absorbing stories in this book is squarely based on facts. It is about the rabbit flea whose life cycle is geared to the hormones of its host. It is a sordid story, co-ordinating rabbit blood and flea copulation. Here we have sex at its seamiest.

Given that its connexion with the biology of sex is rather weak, this Penguin Science Survey can be recommended as a miscellary of interesting topics in biology and allied subjects. URSULA MITTWOCH

MOLECULAR EMBRYOLOGY

Comprehensive Biochemistry

Vol. 28: Morphogenesis, Differentiation and Development. Edited by Marcel Florkin and Elmer H. Stotz. Pp. xii+276. (Amsterdam, London and New York: Elsevier Publishing Company, 1967.) 90s. Pp. xii + 276.

THE contents of this book belie the title of the series to which it belongs. It is in no sense comprehensive, nor could it be at several times the length. Nevertheless it does offer useful reviews of six of the fields from which molecular embryology can expect its first

Monroy reflects an important shift in the biochemical centre of interest in fertilization. Egg-sperm recognition and the mechanisms of contact and penetration are ignored. Oogenesis, and in particular the elaboration of the protein synthetic machinery that will be called into play shortly (in mammals) or more tardily (in many other animals) after cleavage has begun, gets pride of place. Activation and its sequelae are discussed primarily in terms of the controlled de-repression of transcription and translation of genetic information.

Brachet, before discussing nucleic acid synthesis in embryos, provides a succinct and lucid account of the relevant background problems emerging from classical experimental embryology. He, too, is concerned with egg structure, but carries its consequences forward into later embryonic life. He stresses the value of single gene mutants for the analysis of gene regulation during development. For this reason alone the living mammalian egg, now so much more accessible to study than ever before, is certainly about to come into its own.

Both amphibian metamorphosis and embryonic induction have a long history of biological, physiological and chemical analysis. As helpful reviews by Weber and Yamada show, progress in both still seems to be piecemeal, but it is hard to believe that recent and refined biochemical work will not soon be rewarded by a real breakthrough. Articles by Gilbert on the biochemical concomitants of insect metamorphosis and by Scarano and Augusti-Tocco on biochemical pathways in embryos may each usefully draw the biochemist's attention to materials that may be unfamiliar to him.

A year ago Joshua Lederberg asked whether developmental biology might not be cleaned up within the next decade, and suggested that one of the things we should do, if such a timetable appealed, was to concentrate efforts on fewer kinds of animal. He was probably right, and if this volume gives little encouragement for believing that the end is so near, there are signs of increasing preoccupation with the animals and processes that offer the D. R. NEWTH best openings for biochemical attack.

MICROBIAL LIPIDS

The Chemistry and Metabolism of Microbial Lipids By William M. O'Leary. (Monographs in Microbiology.) Pp. xiv+210. (Cleveland and New York: The World Publishing Company, 1967.) \$8.

This monograph has been written primarily for the microbiologist but will also be useful for the biochemist interested in bacterial lipids. The first chapter will be a valuable guide for any microbiologist who considers entering the technically difficult field of lipid chemistry. In this chapter both the effects of varying culture conditions on bacterial lipid composition and the pitfalls associated with the commonly used methods of lipid extraction and identification are discussed in a refreshingly critical manner. Similarly the chapters describing the range of fatty acids and complex lipids occurring in micro-organisms are more than just a routine catalogue of reported data; the author discusses critically the validity of the analytical information that has been presented in the literature.

When Dr O'Leary moves from the subject of lipid chemistry to that of lipid metabolism there is a noticeable change in the standard of this book. The description of the biosynthesis of cyclopropane fatty acids stands out from the rest of this section, as would be expected in view of the author's interest and pioneering studies in this field. The description of the biosynthesis of the saturated and unsaturated fatty acids, however, could have been presented in more detail. During the past few years the individual enzymes of fatty acid synthesis in E. coli have been identified and isolated, and the role of acyl carrier protein in this system has been demonstrated by the elegant studies of Vagelos, Wakil and their coworkers. Whereas reference to this now classical series of investigations only occupies three lines, the discussion of cyclopropane biosynthesis extends to ten pages. Similarly the description of the synthesis of mono-unsaturated fatty acids is marred by the lack of discussion of the enzyme mechanisms involved in the formation of the double bond at the decanoate stage.

Dr O'Leary suggests that his book may well bridge the gap between the inadequate coverage of this field in the more important textbooks and the full review. If there had been a better balance between the sections describing the chemistry and biosynthesis of bacterial lipids the book would have fulfilled this function. The earlier chapters, however, will make an excellent introduction for microbiologists interested in investigating the lipid composition of the specific organisms they are studying. D. GOMPERTZ

PYRAMIDS OF POISON

Pesticides and Pollution

By Kenneth Mellanby. (The New Naturalist: a Survey of British Natural History.) Pp. 221+14 plates. (London: William Collins, Sons and Co., Ltd., 1967.) 30s. net.

DR MELLANBY has obviously used the past few years very valuably indeed and has now produced an informative, comprehensive and balanced account of the whole problem of pollution of our environment. He can say, with conviction backed by long term experiment and observation, just where the dangers of pollution lie now and in the future. Deleterious situations are often allowed to persist long after they have become a public nuisance. serious social dangers are brought to light, somebody, somewhere, has to shout very loudly indeed. Ralph Nader, Barbara Robb and Rachel Carson have, in their various spheres, performed this service for the community. Once public awareness has been aroused sufficiently to devote time and money to the problem, facts must be collected, experiments performed and the real enemy

sought out. To be fair, certain sections of the population and some official bodies were already aware of the problem of widespread pollution, and research in Great Britain was well under way long before Silent Spring was published: nevertheless, it focused public attention on a real and

growing problem.

Pollution of our environment has been with us ever since man lit his first fire. Nevertheless, it is an indictment of the criminal tolerance of man and his indifference to his environment that measures to control pollution are prosecuted with vigour and skill, not according to the level of danger inherent in any one source, but inversely according to the time they have been with us. Dr Mellanby performs another valuable service in showing how generalizations about pollutants may not apply across continents. The British Isles may have, to aggravate any situation. a dense population and an intense agriculture, but they are blessed with a less than fierce sunlight, which can do nasty things to "smog" in Los Angeles, and with insects rarely if ever as voracious as those of Africa or the Americas.

The herbicides and fungicides leave the court virtually unstained. Those responsible for the disposal of radioactive waste, Shell and BP, receive a well-merited pat on the back. The persistent insecticides are shown to be as dangerous as was first feared, for chronic poisoning and synergistic effects between two or more insecticides are now coming to light. A well-merited swipe is directed at Chemicals for the Gardener which recommends a host of dangerous chemicals for unskilled hands to use. garden, like the natural habitat which it begins to approach, does not need routine pest control; both need only the occasional and local rescue programme.

Some sources of pollution are, as Dr Mellanby points out, susceptible to legislation, but how do you legislate against a river which is half sewage effluent? It is staggering to learn that without effluent some rivers might run dry. A new water plan for Great Britain might allow us to use sewage in a more economic way by combining it with comminuted urban waste (the equipment is available) to produce soil compost. Small scale experiments suggest that both pulverized urban waste and pulverized cars can be re-used instead of being dropped on to sea beds to pollute an environment we have not yet reached.

Dr Mellanby is less than fair to the Thames Water Board which in the past three years has never allowed the Thames to become totally de-oxygenated. one-time sewer has shown a remarkable improvement during the past five years. We can be grateful that pollution is not worse than it is in Great Britain, and for this we thank those literate, voluble and knowledgeable conservationists who in the guise of ornithologists, anglers, entomologists and botanists cast a perceptive eye over our countryside at week-ends.

Collins, after this their fiftieth number of the New Naturalist series, should be encouraged to venture again into the constructive and emotive realms of natural history as well as the purely descriptive fields they have served so well in the past. I look forward to publications on such topics as "Recreation with Conservation" and "Water Supplies and the Environment". I hope that the authors of their future volumes will be as lucid and per-B. E. JUNIPER ceptive as Dr Mellanby.

CRAFT INTO TECHNOLOGY

Wood Finishing

By John W. Collier. (Pergamon Series of Monographs on Furniture and Timber, Vol. 6.) Pp. xxiii+306. (Oxford. London and New York: Pergamon Press, Ltd., 1967.) 35s. net.

It is commonly considered that one of the weaknesses of British industry is a failure to bridge the gap between

laboratory and shop floor. The technologist finds it almost impossible to see matters through the factory worker's eyes or to talk in language that he can understand, while the worker thinks of the technologist as remote from reality, with little to contribute to day to day problems.

How refreshing then to find a book written by one with a long practised skill in craft methods who is yet enthusiastic about modern innovations, and who welcomes scientific explanation of what many prefer to regard as craft secrets. In his foreword, addressed to apprentices, journeymen, foremen and managers, Mr Collier writes: "This book is intended to be practical. I do not accept the idea, however, that the practical man need be totally ignorant of technology. Nor do I think that a chemist cannot learn the techniques of application connected with the materials he formulates. I believe the line between theory and practice to be arbitrary and socially undesirable. I have found most chemists to be ready to come more than half way to meet the practical man and it is to be hoped that more practical men will make the necessary effort to understand his materials and the bases upon which they are formulated". These are admirable senti-

Wood finishing, particularly furniture finishing, is in rapid transition from craft to technology. As firms practising it grow larger in size and fewer in number, the leisurely processes of the past are superseded. French polish is today little used, and the stage of interlinked machines, with the various steps of finishing taking place along a conveyor, is now being reached. There is a continuing tendency for the machine to take over more and more from the human operator. In all this, finishing is but following a path long since trodden by more advanced industrial processes.

Until now the books devoted to wood finishing have been very much at the craft level, even when they have advanced to acknowledgment of spray guns and nitrocellulose lacquers. They have been more suited to the individual worker in a small shop than to the finisher involved in a modern production plant. Now we have a book to fill this gap. While not ignoring the older methods, Collier is equally thorough in his treatment of the materials that have emerged from the laboratory in the past dozen years or so, and of the methods of application that have been developed to reduce the manpower so prodigally used by the older ones.

This is a book for everyone concerned with finishing timber for interior use. It is not one to be skimmed at a sitting, but one to be dipped into, to be read in parts, to be digested and to be consulted time and again in the ROSTRON HINDLEY

DEGRADING TIMBER

Timber Pests and Diseases

By W. P. K. Findlay. (Pergamon Series of Monographs on Furniture and Timber, Vol. 5.) Pp. xi+280. (Oxford, London and New York: Pergamon Press, Ltd., 1967.) 30s. net.

In this small, handy book, the author attempts to deal with all the different types of agency which can degrade timber both in the growing tree and after felling. This is an immense task and because of the very wide compass dealt with there are inevitably inequalities in treatment. As might be expected from a co-author of Decay of Timber and Its Prevention, the chapters on timber staining, timber deterioration after felling, decay in buildings, in farms and gardens, and in boats and marine works are well written with good illustrations and straightforward prescriptions for control. Other sections seem less adequate and in the chapter on "Diseases of Standing Trees" for example, stump treatment against Fomes annosus is not well explained. The sections on damage to timber caused by insects are useful summaries of information. It is somewhat surprising, however, in a book where space is at a premium and which is presumably aimed at a mainly British readership, to find eighteen pages devoted to termites.

This book is essentially one for the non-specialist and practical man and it forms a good introduction to the subject of degradation of wood in its entirety.

ANCIENT MEDICINE

Primitive and Archaic Medicine

By Henry E. Sigerist. (History of Medicine I.) Pp. xxi+564. (London and New York: Oxford University Press, 1967.) \$3.50; 24s.

THE contributions of Henry Sigerist as a medical historian are well known. After he left the Chair at Leipzig in 1925 he went to the United States, where he subsequently occupied William H. Welch's Chair in the History of Medicine at Johns Hopkins University. By this time he had clarified his great plan for a history of medicine, global in scope; one that would place medicine in the broad setting of general history and give some indication of the vast part played by the medical sciences among the forces which have determined the progress of mankind. This is the basic explanation of his work as set out by John Fulton in the preface to this volume.

As part of his training to approach this vast task Dr Sigerist followed his classical education with a medical degree, training in historiography, and in addition to an expert knowledge of the languages of Western Europe he devoted several years to the study of Oriental languages and also of Russian.

After fifteen years in the United States he retired at the age of 56 from the Chair at Johns Hopkins and went to live in Switzerland so as to devote his whole efforts to the eight volume history of medicine that he had planned. By the time of his death in 1957 he had completed this first volume on Primitive and Archaic Medicine and also a second volume on early Greek, Hindu and Persian Medicine that was published in 1961.

The first edition of this present volume appeared in 1951 with hard covers. This is a notable second edition as a paper back. In this cheaper and more popular form it will command a wide audience, especially as this republication will draw new attention to the work.

The size and comprehensiveness alone make it very difficult to write a full appraisal of such a volume. It could also be an unwise thing to attempt to particularize details of such a vast and scholarly work.

In this volume of more than 500 pages we are able to read and appreciate a unique presentation of primitive and archaic medicine and to realize that until barely a century ago much of what could be thought archaic was still practised. Indeed, there are still relics and names of primitive medicine in our daily life and work.

The outstanding feature in this volume is the presentation of medicine in Ancient Egypt. Here alone one sees how the development of medicine is intimately mixed with the passage of history itself. This fascinating account of Ancient Egypt and the simple clear presentation of its history are followed by an equally enthralling account of Mesopotamian medicine. Each chapter in the work is followed by an invaluable and impressive biblio-

It is to be hoped that the second volume will in due course appear in the same form as this one. We can only regret that Dr Sigerist's death has prevented us from reading and enjoying the remaining volumes that would have completed his grand plan.

EVOLUTION FOR ALL

Understanding Evolution

By Herbert H. Ross. (A Spectrum Book.) Pp. ix+175. (Englewood Cliffs, N.J., and London: Prentice-Hall, 1966.) 20s.

This book is a remarkably successful attempt to give an account of evolution from the possible modes of beginning of the universe down to the production of man and such extremely recent phenomena as industrial melanism, all done in 165 pages of text with numerous illustrations, yet very readable. The ten principal divisions of the book deal with: history of evolutionary thought; evolution of the universe; life's nature and origin; the progress of life; passage through time (including opportunism, survival and extinction); variation and natural selection; increase in the number of species; the geotectonic factor (influence of the major geological events on evolution); evolution of ecological communities; and progression of change (summary). The width of treatment is unusual and extends to constituent topics as well—it is pleasant to find an author who does not spend his whole space for speciation on geographical speciation—yet in those topics of evolution that I know something about the treatment is remarkably comprehensive and clear although condensed, and very up to date. It would be easy, no doubt, to disagree over some points of emphasis or details of fact or omission, but most of those I have noted seem to me trivial in comparison with the good points of the book. It should be looked at by anyone seeking a good (and cheap) text for students and for non-biologists. A. J. CAIN

OBITUARIES

Dr Douglas McClean

Douglas McClean, bacteriologist in charge of the Vaccine Lymph Department of the Lister Institute of Preventive Medicine for twenty-five years, died in Oxford on July 10. He was born on May 13, 1896, in Constantinople, where his father was at the time medical superintendent at the British Seamen's Hospital. At the age of nine he came to England, where he was at school until he went to St. Thomas's Hospital in 1914. His medical training was interrupted by three years service as surgeon probationer in the Harwich Force of the Royal Navy, which left a permanent somewhat nautical stamp on him. He returned in 1919 to complete his training, and in 1924 took up the post of pathologist at Great Ormond Street Hospital for Sick Children.

Although he had a real interest in clinical problems he was irked by the inadequacy of current knowledge about the causation and especially the prevention of infective disease, and in 1928 he went to work under Dr (later Sir John) Ledingham at the Lister Institute at Chelsea. Here he was introduced to the study of viruses, especially vaccinia, and in 1930 he was appointed assistant bacteriologist in the Institute's serum department at Elstree. In producing vaccine lymph it was the practice to infect the skin of sheep with seed vaccine prepared in rabbit testicles, and McClean observed that uninfected testicular extracts had a remarkable capacity to enhance the diffusion of substances injected into the skin. His first paper on the phenomenon was published in 1930, and heralded a series of studies on the action of "spreading factor" and its possible role in microbial invasion, in fertilization and in therapeutics. He did not himself characterize the factor as a hyaluronidase, nor was he the first to demonstrate its production by bacteria, but his observation, which was contemporary with a similar independent observation by Duran-Reynals; opened up a new field of research and was a contribution to the recognition that bacterial toxins might be specific enzymes, which was first proved by M. G. Macfarlane and and B. C. J. G. Knight, also at the Lister Institute, in the case of the lecithinase of Clostridium perfringens. McClean became bacteriologist in charge of the vaccine lymph department in 1936, in which role he made a number of significant improvements in the production and stabilization of vaccine lymph, especially by devising a means of virtually eliminating contaminating bacteria by treatment with phenol.

Despite his critical yet enthusiastic approach to his scientific work, the execution of which he thoroughly enjoyed, he never wholly abandoned what might be called an amateur status, and refused to allow science (or administration, which he did well) to exclude his other interests. He enjoyed his garden, his bees, and good conversation—especially accompanied by good wine, of which he was a connoisseur. He shared with his wife (a well known writer and illustrator of children's books) a circle of artistic friends. Finally, he was a firm advocate of socialist principles—and an equally firm upholder of civil liberties—and he found an outlet for an important part of his energies in promoting the work of the Association of Scientific Workers.

J. H. Humphrey

University News:

Massachusetts Institute of Technology

PROFESSOR HARRY C. GATOS, at present both professor of electronic metallurgy in the Department of Metallurgy and Materials Science and professor of molecular engineering in the Department of Electrical Engineering, has been appointed associate director of the Center for Materials Science and Engineering.

Reading

DR P. G. Hall, at present reader in geography at the London School of Economics and Political Science, has been appointed to the chair of geography in succession to Professor T. G. Miller, who has been appointed principal of the University College of Rhodesia.

Appointments

SIR STANLEY BROWN, chairman of the Central Electricity Generating Board, has been elected president of the Institution of Electrical Engineers for the session 1967-68. The chairmen of the three divisions of the institution have also been elected as follows: DR E. EASTWOOD, director of research for English Electric, chairman of the Control and Automation Division; MR J. H. H. MERRIMAN, senior director of engineering in the Post Office, London, chairman of the Electronics Division; MR E. C. RIPPON, director of C. A. Parsons and Co., Ltd., Newcastle upon Tyne, chairman of the Power Division.

ADMIRAL O. A. QUIHILLALT of Argentina has been elected chairman of the new Board of Governors of the International Atomic Energy Agency, and Mr N. Ivanchev, governor from Bulgaria, and Miss L. Roesad, governor from Indonesia, have been elected vice-chairmen.

Announcements

THE Lalor Foundation makes annual awards to investigators for the study of basic phenomena and mechanisms in the field of reproductive physiology, and the 1968 programme of awards will give priority to applied scientific and clinical research on intra-uterine phenomena, uterine peristalsis in relation to implantation, early gestation and its control, clinical research on the physical sequelae of abortion, and the like. Further information about these awards can be obtained from the Director, Lalor Foundation, 4400 Lancaster Pike, Wilmington, Delaware.

Meetings

476TH Meeting of the Biochemical Society, November 18, Medical Research Council Laboratories, Carshalton (Executive Secretary, The Biochemical Society, 7 Warwick Court, Holborn, London, WC1).

FLUORO-ORGANIC Chemistry, March 28-29, 1968, University of Birmingham (Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London, SW1).

AUTHORITY and Leadership Working Conference, March 29-April 11, 1968, Leicester (Conference Secretary, Centre of Applied Social Research, Tavistock Centre, Belsize Lane, London, NW3).

BIOLOGY of Reproduction in Mammals, April 9-11, 1968, Nairobi (Professor E. C. Amoroso, Department of Physiology, Royal Veterinary College, University of London, Royal College Street, London, NW1).

MARINE Food Chains, July 23-27, 1968, University of Aarhus (Dr J. H. Steele, Department of Agriculture and Fisheries for Scotland, Marine Laboratory, P.O. Box 101, Victoria Road, Aberdeen.

HAEMOPHILIA, August 26-28, 1968, Montreal (The World Federation of Haemophilia, 122 Arlington Avenue, Montreal 6, Quebec).

CORRESPONDENCE

Informed Chemists

Sm,—It is encouraging to those like myself working on the bibliographical side of science to read in a recent issue (Nature, 215, 1324; 1967) that British chemistry PhD students are to be kept up to date by computer. The students will all be in their third year and this should mean that they carry the resulting familiarity with mechanized information services over into their future jobs.

In planning this exercise, one wonders why the Office for Scientific and Technical Information thought it necessary to select and train six liaison officers to act as regional agents. Why not make use of university library staffs, already to some extent conversant with local research projects, with far better lines of communication into local chemistry departments and already working in the documentation field? Does OSTI not know that British university libraries already act as local agents for other computerized information services such as that for medical literature (MEDLARS) and that many of them are developing courses on documentation for PhD students, chemists included, which would make an ideal platform for promulgating schemes such as this?

I recognize that the scheme is an experiment, run in conjunction with the Chemical Society's Research Unit in Information Dissemination and Retrieval at Nottingham University. But in an experiment on such a scale and especially one designed also to influence people's future actions, why not normalize as far as possible the business of getting students to describe their research project in terms of an array of subject headings? This is rarely as painless as it sounds. It would be a pity if experience of a rather remotely controlled experiment in information dissemination like this were to put students off the kind of information services, based on libraries, which will be available to them later on in industry or Government research.

Yours faithfully,

R. J. DANNATT

University of Strathclyde, Andersonian Library, Glasgow, C1.

Towards a Broader Curriculum

SIR,—Few engineers would disagree with the spirit of the Declaration of the Cambridge Conference on a Broader Curriculum in sixth forms reported in your columns of 23rd September (Nature, 215, 1329; 1967), or underestimate the seriousness of any failure to solve the many educational problems involved. D. W. Hutchings in a recent survey for CRAC found that only 137 out of 2,006 science and technology students at 5 major universities had obtained an "A" level in an arts subject.

Priority appears to have been given at the Conference,

not unnaturally, to the interface between schools and university, but Dr. Nichol drew attention to looking at education as a whole, and this entails a closer look at the social needs of the country whose taxpayers, after all, foot the bill directly or indirectly. The end point of schools is too apt to be conditioned by the number of university places obtained, irrespective of the suitability of the discipline entered in relation to its later value. Equally important would seem to be the interface between university and the field of postgraduate employment.

It is so often said that universities would be ready to change curricula if they only knew what the customer really wanted, but that the industrial customer gives conflicting requirements. It is suggested that an extensive survey is needed over the whole field of technology on the lines of that conducted in 1961 by Professor Edgeworth Johnstone for chemical engineers, and in 1964 by Professor Hutton and Dr Gerstl for mechanical engineers. recent CEI/Ministry of Technology survey of 20,000 professional engineers has already shown the superior earning capacity over the £2,000 mark of graduates compared with non-graduates. A further survey conducted in conjunction with other learned societies could yield much of value.

The Hutton/Gerstl survey covering 387 mechanical engineering graduates revealed that the usage of subjects in the practice of their profession ranked in the ordermathematics, engineering drawing, technical report writing, applied mechanics, properties and strength of materials, industrial administration, followed by some fourteen technical subjects with foreign language rating last. But when asked to suggest an ideal course the general opinion favoured a time distribution of

Basic Engineering Sciences, e.g., strength of materials Fundamental Sciences (maths, physics, chemistry)	$\frac{27\%}{23\%}$
English and Humanities 7% Technical Report Writing 7% Foreign Languages 7%	21%
Foreign Languages 7%)	13%
Design Engineering Industrial administration, economics, social science	10%
Speciality engineering, e.g., instrument or textile	6%

which illustrates that these engineers themselves were well aware of the great importance of non-technical subjects, particularly of communication, and of the danger of blinkered curricula. Maybe the doctor provides the remedy, but the patient can at least indicate the symptoms; a similar survey of graduates qualified in the last 10 years, say, including Dip.Techs., might reveal a great many worrying symptoms, with the need for much greater liaison between universities and industry.

Mr Morrison's suggestion of five subjects for university entry prompts the question of whether consideration has been given to the suitability of the proposed European International Baccalaureat.

Any changes in curricula, however, will only be pipe dreams unless an adequate number of well qualified maths and science teachers is forthcoming. The CEI/Ministry of Technology survey indicates that the salaries of maths and science (men) graduate teachers in maintained schools were below those for graduate engineers, particularly after the age of 38.

Yours faithfully,

I. G. AYLEN

21 Ovington Square, London, SW3.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, October 16

ROYAL INSTITUTION (at 21 Albemaric Street, London, W1), at 1.15 p.m.—Professor George Porter, FRS: "The House of Michael Faraday".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, SW1), at 5 p.m.—Mr N. W. Hussey: "Prospects for Integrated Control in Protected Cultivation".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 5 p.m.-Professor G. W. Robinson: "Why is Oxygen Blue?" (Bourke Lecture).

BRITISH COAL UTILIZATION RESEARCH ASSOCIATION (at the Institution of Civil Engineers, Great George Street, London, SW1), at 5.30 p.m.—Mr Harry Perry: "Current Coal Utilization Research in the USA" (Sixteenth Coal Perry: "Current Science Lecture).

Institution of Mechanical Engineers, Internal Combustion Engines Group (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "North Sea Gas—Internal Combustion Engines".

Tuesday, October 17

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY (in the Department of Mechanical Engineering, Exhibition Road, London, SW7), at 5.80 p.m.—The Rt. Hon. Anthony Wedgwood Benn, MP: "The Government's Policy for Technology".

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the AUTO-MATIC CONTROL GROUP of the INSTITUTION OF MECHANICAL ENGINEERS, at Savoy Place, London, WC2), at 5.30 p.m.—Discussion meeting on "Control Aspects of Synchronous Machine Dynamics" opened by Dr W. D. Humpage.

UNIVERSITY OF ASTON IN BIRMINGHAM (at Gosta Green, Birmingham, 4), at 5.30 p.m.—Professor A. J. Ede: "Blowing Hot and Cold—Some Reflections on Research in Heat Transfer" (Inaugural Lecture).

University of London (at King's College, Strand, London, WC2), at 5.30 p.m.—Professor R. M. H. McMinn: "The Cellular Anatomy of Tissue Repair" (Inaugural Lecture).

UNIVERSITY OF LONDON (at Senate House, London, WC1), at 5.30 p.m.— Lord Florey: "Elements of the Vascular System". (First of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

Institution of Mechanical Engineers, Railway Engineering Group (at 1 Birdcage Walk, Westminster, London, SW1), at 6 p.m.—Discussion Meeting on "Use of Fluidics in Control Systems".

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (at 14 Belgrave Square, London, SW1), at 6 p.m.—Dr J. Heyboer: "Modulus and Damping of Polymers in Relation to their Structure".

UNIVERSITY OF LONDON (at the Linnean Society, Burlington House, Piccadilly, London, W1), at 6.30 p.m.—"The Historical Background to Modern Botany" by various lecturers. (Further lectures on October 24, 31, November 7, 14, 21, 28, December 5 and 12.)

Wednesday, October 18

INSTITUTION OF ENGINEERING INSPECTION (at the Royal Institution, The University of Liverpool), at 9.45 a.m.—Symposium on "APractical Approach to Reliability Engineering".

PHOTOBIOLOGY GROUP (in the Physics Department, Imperial College, London, SW7), at 2.30 p.m.—Meeting on "Vision and Photosynthesis".

GEOLOGICAL SOCIETY OF LONDON (at the Shell Centre, Belvedere Road, London, SE1), at 5 p.m.—Dr J. M. Harrison: "Geological Sciences in the World Scientific Community" (21st William Smith Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Discussion Meeting on "Road Heating with particular reference to UK Practice" opened by Mr W. M. Craig.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr J. H. H. Merriman, OBE: "Men, Circuits and Systems in Telecommunications" (Chairman's Inaugural Address).

SOCIETY OF INSTRUMENT TECHNOLOGY (at the A.E.I. Cinema, 33 Grosvenor Place, London, SW1), at 5.30 p.m.—Mr H. Edmonds-Brown: "Flame-proofing, Intrinsic Safety and their Engineering Implications".

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, London, SW7), at 6 p.m.—Mr N. C. Cordingly: "The Design of a Clean Room for Making Special Vacuum Tubes".

INSTITUTE OF INFORMATION SCIENTISTS (at Knightway House, 20 Soho Square, London, W1), at 6.15 p.m.—Dr A. J. Harley: "The UK MEDLARS Service".

OIL AND COLOUR CHEMISTS' ASSOCIATION, LONDON SECTION (in the Engineering Lecture Theatre, University College London, Torrington Place, London, WC1), at 6.30 p.m.—Dr F. L. Dolton: "The Irradiation Curing of Paint Films".

SOCIETY FOT ANALYTICAL CHEMISTRY, MICROCHEMICAL METHODS GROUP t "The Feathers", Tudor Street, London, EC4), at 6.30 p.m.—Discussion (at "The Meeting.

Wednesday, October 18-Friday, October 20

SOCIETY OF DYERS AND COLOURISTS (at the Palace Hotel, Torquay, Devonshire)—Symposium on "The Impact of Automation and Instrumentation in the Colour-using Industries".

Thursday, October 19

SOCIETY FOR ANALYTICAL CHEMISTRY, BIOLOGICAL METHODS GROUP (at the Royal College of Physicians, 11 St Andrew's Place, Regent's Park, London, NW1), at 10 a.m.—Symposium on "Aspects of Toxicity Testing".

University College London (in the Anatomy Theatre, Gower Street, London, WC1), at 1.20 p.m.—Professor J. Z. Young, FRS: "Memory".*

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 2.30 p.m.—Professor Ronald King: "Radiation and the Structure of Matter" (Civil Service Lecture).

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W1), at 5 p.m.—Professor M. R. W. Rey (Paris): "Early Development of the Copper Segregation Process"; Mr E. T. Pinkney and Mr N. Plint: "Treatment of Refractory Copper Ores by the Segregation Process".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W1), at 5 p.m.—Mr N. Jardine: "What is Homology?"; Mr J. D. Holloway and Mr N. Jardine: "New Methods in Zoogeography".

UNIVERSITY OF LONDON (at the Royal Postgraduate Medical School, Wolfson Institute, Du Cane Road, London, W12), at 5 p.m.—Professor E. B. Chain, FRS: "Biochemical Research and Progress in Medicine".

INSTITUTE OF PETROLEUM, EXPLORATION AND PRODUCTION GROUP (at 61 New Cavendish Street, London, W1), at 5.30 p.m.—Mr Richard L. Jodry "Pore Geometry of Carbonate Rocks".

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the AUTO-MATIC CONTROL GROUP of the INSTITUTION OF MECHANICAL ENGINEERS, at the Institution of Electrical Engineers, Savoy Place, London, WC2), at 5.30 p.m.—Mr D. J. Kyte: "The Automation of Colour Reproduction in Printing".

UNIVERSITY OF LONDON (at the Institute of Child Health, Guilford Street, London, WC1), at 5.30 p.m.—Professor E. Jean Hanson: "The Molecular Structure of Muscles in Relation to the Mechanism of Contraction". (Second of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, SE1), at 6 p.m.—Mr T. J. R. Cooper: "The Application of Refrigeration to the Bacon Industry".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS (at 8-9 Bedford Square, London, WC1), at 6 p.m.—Symposium on "Management, Methods and Media in Electronic Training at the School of Electronic Engineering, REME, Arbordeld". Speakers: The Commandant, Colonel H. G. Frost. and members of his staff.

SOCIETY OF CREMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, SW1), at 6 p.m.—Mr C. J. Keattch and Mr J. A. Reynolds: "The Analysis of Concrete—Problems in Determining the Fourth Ingredient".

BRITISH INSTITUTE OF RADIOLOGY (at 32 Welbeck Street, London, W1). at 6 p.m.—Discussion Group, 8 p.m.—Dr R. D. Hoare: Presidential address.

Friday, October 20

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W(2), at 10.30 a,m.—Colloquium on "Interface Problems in the Calibration of R.F. Instruments".

ROYAL INSTITUTION, PHOTOCHEMISTRY DISCUSSION GROUP (at 21 Albemarle Street, London, W1), at 1 p.m.—Dr E. Vander Donckt (University of Brussels): "Charge Distributions and Free-Energy Relationships in Excited States".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, $W(^2)$, at 5.80 p.m.—Discussion Meeting on "Testing and Specification of Integrated Circuits".

BIOLOGICAL ENGINEERING SOCIETY (in the Botany Theatre, University College, Gower Street, London, WC1), at 6 p.m.—Professor A. F. Huxley, FRS: "Forgetting and Rediscovery in Physiology" (Woolmer Memorial Lecture)."

ROYAL INSTITUTION (at 21 Albemarle Street, London, W1), at 9 p m. - The Rt. Hon. George Woodcock, CBE: "Trade Unions".

Friday, October 20-Saturday, October 21

BIOCHEMICAL SCOIETY (at the National Institute for Medical Research, The Ridgeway, Mill Hill, London, NW7)—475th Meeting. Programme will include a Colloquium on "Functions of Nucleic Acids in the Cytoplasm" and sessions for the presentation of communications.

Saturday, October 21

FISHERIES SOCIETY OF THE BRITISH ISLES (at the Zoological Society of London, Regent's Park, London, NW1), at 2.30 p.m.—Inaugural Meeting.

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, SE23), at 3.30 p.m.—Professor Johannes Nicolaisen (University of Copenhagen): "The Tuareg—Veiled Men of the Sahara".*

Monday, October 23

INSTITUTION OF INDUSTRIAL SAFETY OFFICERS (in the Lecture Theatre, Institution of Civil Engineers, Great George Street, London, SW1), at 2 p.m.—Mr W. A. Wood: "The Application to Industry of Recent Advances in Accident Prevention in the Mining Industry" (Alexander Redgrave Memorial Lecture).

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Council Room of the Science Museum, Exhibition Road, London, SW7), at 5.30 p.m.—Mr J. D. North: "Eclipses and Eclipse Computers in the Ptolemaic Tradition".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Mr C. M. Van der Burgt: "Materials for Ultrasonic Delay Lines".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, WC2), at 5.30 p.m.—Professor A. Stratton: "Inertial Navigation".

UNIVERSITY COLLEGE LONDON (in the Botany Theatre, Gower Street, London, WC1), at 5.30 p.m.—Dr R. J. Smeed: "Traffic Studies and Urban Congestion".*

University of London Institute of Education (in the Great Hall, King's College, Strand, London, WC2), at 5.30 p.m.—Professor G. H. Bantock: "The Idea of a Liberal Education".*

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, WC2), at 6.30 p.m.—Dr A. H. Cookson "Compressed Gas as High Voltage Insulation" (Chairman's address).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the

APPLICATIONS are invited for the following appointments on or before the dates meutioned:

RESEAROH FELLOW (graduate with a higher degree or relevant research experience) in CONTROL ENGINEERING in the DEPARTMENT OF ENGINEERING, for studies in the development of methods of stability analysis of non-linear systems—The Registrar, The University, Leicester (October 25).

SENIOR LECTURER/LECTURER IN GEOGRAPHY in the School of Earth Sciences, Macquarie University (the appointment will be made within the field of human geography)—The Secretary-General, Association of Commonwealth Universities (Branch Office), Mariborough House, Pail Mall, London, S.W.1; or The Registrar, Macquarie University, Eastwood, New South Wales, Australia (October 30).

CHAIR OF PHYSICS—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (October 31).

LECTURER OF ASSISTANT LECTURER IN THE DEPARTMENT OF PSYCHOLOGY—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (October 31).

RESEARCH ASSISTANT (honours graduate in engineering or science) in MECHANICAL ENGINEERING in the STRUCTURAL MECHANICS RESEARCH GROUP which is principally concerned with the study of the stable and unstable behaviour of thin-walled structural sections—The Assistant Registrar (Establishment), University of Sussex, Falmer, Brighton, Sussex (October 31).

SENIOR LECTURER or LECTURER in PLANT ECOLOGY in the DEPARTMENT OF BOTANY, University of the Witwatersrand, Johannesburg—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, SW1 (South Africa and London, October 31).

RESEARCH ASSISTANT (graduate in metallurgy, geology or physics) in METALLURGY, to work on metallographic aspects of meteorite material using conventional metallographic methods in conjunction with a SEM 2 electron probe microanalyser—The Registrar, University of Manchester, Manchester 13, quoting Ref. 157/87/Na (November 9).

SENIOR LECTURER or SENIOR LECTURER in Sciolilogy in the DEPARTMENT o

JOHN INNES CHAIRS OF GENETICS AND APPLIED GENETICS in the School of Biological Sciences—The Registrat, University of East Anglia, Earlham Hall, Norwich, NOR 88C (November 30).

DEPARTMENTAL DEMONSTRATOR IN ANIMAL ECOLOGY—Professor J. W. S. Pringle, Department of Zoology, Parks Road, Oxford (November 30).

UNIVERSITY LECTURER IN ANIMAL ECOLOGY in the DEPARTMENT OF ZOOLOGY—The Secretary of Faculties, University Registry, Broad Street, Oxford (November 30).

LECTURER (with a special interest in power systems) in the DEPARTMENT OF ELECTRICAL ENGINEERING, to teach up to postgraduate level and to undertake original work—Professor J. H. Calderwood, University of Salford, Salford 5, Lancs.

PHYSICAL CHEMIST (preferably with research experience in the field of

undertake original work—Professor J. H. Canderwood, University of Sahotu, Salford 5, Lancs.

Physical Chemist (preferably with research experience in the field of polymer characterization, optical studies or electrical behaviour) to join a group concerned with long-range research into the study of new materials—The Personnel Officer, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian, Scotland.

Physiologist, Biochemist or Biologist (with a good honours degree) to assist with research in physiological, biochemical and cell culture studies of isolated mammalian nerve cells—Dr H. Hillman, Department of Biological Sciences, University of Surrey Annux, 14 Faicon Road, London, SW11.

RESEARCH ASSISTANT (with a degree or equivalent qualification and preferably previous experience in crystallography or electronic computing) in the Department of Hongamic and Surreyard Chemistry, to assist the group of research workers engaged in the field of X-ray crystallography—Professor H. M. N. H. Irving, The University, Leeds, 2.

SENIOR LECTURER (preferably with experience or interest in mineralogy, petrology or geochemistry) in Geology—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N7.

A View of the Brain

J. S. GRIFFITH

This book contains a development of the author's new theory of the functional organization of mammalian and human brains at their highest levels. It is the first book in a new series, Oxford Science Research Papers, designed to make results in various fields available with the minimum of delay and to provide a medium for short authoritative surveys incorporating original work. Numerous text figures paper covers 15s. net. Oxford Science Research Papers

Key to the Families of Flowering Plants of the World

Revised and Enlarged for use as a Supplement to *The Genera of Flowering Plants* J. HUTCHINSON

This is a revision and rearrangement of the Key to the Families included in the author's Families of Flowering Plants. The separate key is intended for use with his Genera of Flowering Plants but will be found very useful by itself. 6 text figures 30s net (paper covers 18s net)

Megalithic Sites in Britain

A. THOM

Here is new evidence for the sophisticated astronomical and mathematical knowledge of the primitive peoples who built Stonehenge and thousands more megalithic monuments some 4,000 years ago.

Professor Thom provides convincing data to show that many of the great stone circles were used for observing the movements of the sun and the moon, and for time-keeping. 1 plate, 76 text figures 63s net

Contact and Frictional Electrification

W. R. HARPER

Dr Harper shows that the circumstances in which electrification appears provide the clues which enable the phenomena to be brought into line with solid state theory. 111 text figures 70s net

APPOINTMENTS VACANT

UNIVERSITY OF MANCHESTER MANCHESTER, 13

RESEARCH ASSISTANT IN **METALLURGY**

Applications invited from graduates in metal-Applications invited from graduates in metallurgy, geology or physics to work on metallographic aspects of meteorite material using conventional metallographic methods in conjunction with a SEM 2 electron probe microanalyser, Appointment for one year in first instance from December 1, 1967, but would be renewable for up to three years. Salary range £1,000 to £1,250 per annum.

Application forms (returnable by November 9) and further particulars from Registrar. Quote ref. 157/67/Na. (1130)

THE UNIVERSITY OF LEEDS

DEPARTMENT OF CHEMICAL PATHOLOGY

Applications are invited from either medically or scientifically qualified candidates for appointment as Lecturer at a salary on the scale £1,580 to £2,700 (efficiency bar £2,260) for medically qualified lecturer or £1,470 to £2,630 (efficiency bar £2,270) for a scientifically qualified lecturer. Initial appointment at any point on the scale. Duties involve work in the hospital blochemistry laboratory which the department runs for the General Infirmary at Leeds. The Lecturer will be expected to spend half his time in research, and may work for a higher qualification. The department may be visited by arrangement with Professor G. H. Lathe. Applications are invited from either medically

Applications (three copies), stating age, qualifications and experience and naming three referees, should reach the Registrar and Secretary, the University, Leeds, 2 (from whom further particulars may be obtained), not later than October 23, 1967.

UNIVERSITY OF QUEENSLAND SENIOR LECTURER IN PSYCHOLOGY

SENIOR LECTURER IN PSYCHOLOGY

The University invites applications for the above-mentioned position. Applicants should hold a higher degree in psychology and preferably should have some training in applied or statistical mathematics. The applicant should have teaching and research experience in one or more of the following fields—test construction, multidimensional scaling, psychometric methods, mathematical psychology, factor analysis, computer applications, experimental design. The appointee will be responsible for the direct supervision of Ph.D. candidates in this area (4 at present), and assistance in the general supervision of experimental design for graduate and doctoral research. He will also be responsible for the overall supervision of teaching in statistics and psychometrics in the Department. The salary range for a Senior Lecturer is \$A6,400 by \$A200 (6) to \$A7,600. Academic salaries are at present under review and the proposed salary range for a Senior Lecturer is \$A7,550 to \$A8,750. The University provides Superannuation similar to F.S.S.U., Housing Assistance, Study Leave and Travel Grants.

Additional information and application forms will be supplied upon request to the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in London and Brisbane on November 17, 1967. (1231)

GAS CHROMATOGRAPHY MASS SPECTROMETRY

An Internation organization producing and marketing a GC-MS system requires a Product Manager to lead its sales efforts in the U.K. and to exploit the potential which has been shown to exist for this type of instrument. As seen below a great deal is required from the successful applicant but the rewards and conditions are in keeping.

Required

- I. A scientist interested in marketing.
- 2. Experience in G.L.C. work.
- 3. An understanding of and preferably experience in mass spectrometry.
- 4. Some knowledge of data handling.
- 5. An interest in discussing applications with prospective users.
- 6. Experience in application work.
- 7. A desire to use initiative.
- 8. The will to see sales objectives achieved.
- 9. Be prepared to travel extensively in the U.K.
- 10. Be resident in or prepared to move to London or Home Counties.

Offered

- I. A position in a young and enthusiastic company.
- 2. An instrument for application work.
- 3. A salary in the region of £2,000 per annum.
- 4. Full technical support.
- 5. Excellent working conditions including three weeks holiday p.a.
- 6. Participation in superannuation scheme.
- 7. Use of a company car.

Interested applicants should send full particulars of their career and experience to G.M.N., Box No. 939, Nature, T. G. Scott and Son Ltd., 1 Clement's Inn, London, W.C.2.

JOINT APPOINTMENT

THE UNIVERSITY OF LIVERPOOL FACULTY OF MEDICINE THE ELECTRICITY COUNCIL RESEARCH CENTRE, CAPENHURST

RESEARCH FELLOW IN HUMAN PHYSIOLOGY

The University of Liverpool and the Electricity Council seek applications for the post of Research Fellow in Human Physiology.

The successful candidate will join a team drawn from a number of disciplines, being set up at the Electricity Council Research Centre to enquire into factors which establish human comfort in home or office environment.

The Fellow will be granted an Honorary Lectureship in Physiology in the Faculty of Medicine at the University of Liverpool and will be expected to engage in research and in teaching in the Departments of Surgery and Physiology. His research in the Department of Surgery will be closely related to the work at Capenhurst and will be concerned with problems of environment in relation to the peripheral circulation in health and disease.

The appointment will be based at E.C.R.C. at Capenhurst which is 18 miles from the University with excellent transport links.

Generous facilities are available at E.C.R.C. and there is already liaison between the two organizations.

Salary range: £1,885-£2,530 £2,490-£3,085

Please reply to: MR. D. C. PAGE, Head of Personnel Services, Electricity Council Research Centre, Capenhurst, Chester, quoting ref. No. N/96.

or to MR. D. ANNIS, M.D., F.R.C.S., Department of Surgery, The University of Liverpool, 48-52 Bedford Street North, Liverpool, 7.

NATURE Volume 216 OCTOBER 21, 1967

Dark Horse Run Well

THE appointment of Dr John McGregor Hill as chairman of the United Kingdom Atomic Energy Authority had not been widely anticipated, but it is none the less welcome on that account. To say the least of the occasion, it puts an end to the uncertainty there has been about a successor to Lord Penney and is thus, by extension, an assurance to those on the authority's payroll who may have feared that they would read one day in the newspapers that the anxieties of the past several years had suddenly culminated in the disappearance of the authority by means of some administrative sleight of hand. Now there is at least some tangible evidence that the authority will remain in being, for a time at least. Indeed, the fact that Dr Hill has been the member of the authority responsible for production will be taken by many people to be a sign that the authority will now be able to make come true some of the dreams which Lord Penney shared with the Select Committee on Science and Technology earlier this year. Dr Hill's appointment will, in particular, be regarded as a token that the authority is about to become the king-pin in a national organization for designing and even for constructing ever more advanced and successful nuclear power In the circumstances, it is wise if also obligatory that Dr Hill should have spent his first few days in office insisting that it is far too soon to know what will really happen in the years ahead. problem, of course, is plain enough, and Dr Hill will not have to spend much time on its definition. The real need is for a bright and quick solution.

The view that the authority has outlasted its original objectives is a truism but also an over-simplification, which implies that it is not a particularly valuable guide to action. Dr Hill's great difficulty stems from the way in which an organization which as recently as ten years ago was united-or reasonably well unitedin the pursuit of a few identifiable objectives has become fragmented. Military nuclear energy in Britain is no longer important enough to keep Aldermaston anything like fully occupied. The need for basic research as a support for reactor development is not urgent enough to occupy more than a part of the energy of Harwell. The people who make fuel rods seem happy enough, and the uranium enrichers are even increasing the scale of operations at Capenhurst so as to be able to manufacture fuel for advanced gas cooled reactors. But in spite of their successes, the design and development teams at Risley in Lancashire must be wondering what there will be for them to do in the mid-seventies, when the prototype advanced reactor will have been working for some years. It is no wonder that their ambition is to occupy the centre of the stage in the nuclear energy boom which may dominate the seventies. The trouble, of course, is that if Dr Hill tries to keep everybody happy, he will be perpetuating a form of organization the several parts of which can only be harmed, in some sense or another, by perpetual co-existence.

The problem of the research establishments is separable, almost in the literal sense, and the annual report of the authority for 1966-67 (see Nature last week) is by itself a reminder that vigorous steps must soon be taken to make more effective use of the great talents at present built into Harwell and Aldermaston. For some years the authority has been hoping to keep the Harwell laboratory in being by diversifying the work it does and, in particular, by encouraging the laboratory to take on research contracts with industrial companies. Further opportunities for diversification were provided by Section 4 of the Science and Technology Act (1965), for this enabled the Minister of Technology to direct the public laboratories in his charge to undertake specific programmes of research and development. It is only natural that the laboratories themselves have usually taken the initiative in suggesting suitable subjects for a ministerial directive. Expenditure under this heading amounted to £772,000 in the financial year just finished, while the cost of research on behalf of customers other than the British Government worked out at £383,000. On the face of things, this may seem a respectable achievement, although the sums involved are small compared with the annual expenditure on research and development which works out at £50 million. In reality, however, there is at least a danger that the programme of diversification may be a backward and not a forward

Although at this stage it would be wrong to write . off the policy of diversification as a failure, there is no doubt that it raises serious and unanswered questions about the relationship between industrial research and commercial success. As well as being a means of providing laboratories with work to do, diversification is also considered as a means of providing particular industries and even companies with research and development which are at present neglected. But the experience of the research associations, which are kept in being by the membership subscriptions of commercial enterprises, shows that in matters like these it is easier to produce the results of research than to persuade potential beneficiaries to take notice of them. It remains to be seen whether Harwell and Aldermaston will succeed where several experienced research associations have failed or almost failed. It is also hard for outsiders to appreciate what good purpose may be

served in the arrangement whereby Harwell has been asked by the Science Research Council to assist in the design of a radio-telescope, and by the Medical Research Council to undertake the development of an ultracentrifuge. Would it not have been better, in the long-term interests of the British economy, if contracts for these operations had been placed with companies in a position eventually to put the products concerned on the commercial market? There is at least a case to answer. And whatever the truth may be, there is no reason why uncertainty about the future of these laboratories should be perpetuated simply because one or two per cent of their combined activity is now occupied on projects brought in under Section 4.

The simple solution is to transfer both laboratories from the authority to the Ministry of Technology—although Aldermaston might go to the Ministry of Defence instead. But this is only half a solution. In the long run some means must also be found for encouraging people at the two laboratories to find jobs for themselves in industry. The Jones report on the brain drain had useful suggestions to make along lines like these. Dr Hill could do worse than spend half an hour reading what the Jones Committee had to say. The prize for a successful redeployment of the authority's unwanted talent would be a powerful and rapid strengthening of industrial research and development in Britain.

The reorganization of the industrial empire will be an even more hazardous undertaking. The penalties of serious error are potentially enormous. It is plain that the months ahead will be crucial for the development of nuclear energy in Britain and in the export trade. It is also clear that there are too many design teams chasing too few contracts for completed power stations. But does it follow that there is merit in the obvious and tidy solution of amalgamating all this effort under the umbrella of an atomic energy authority more deliberately oriented towards commercial con-

Boom in British Electronics

THE pace of advance in electronics is now quite remark-Lable. Fewer than twenty years have passed since the invention of the transistor, but already the electronics industry has crucial strategic importance even in the British economy. One result of the rapid expansion has been an extraordinary reduction in prices-a transistor which cost £15 in the early fifties can now be had for 1s. $7\frac{1}{2}d$. Another has been the complete domination of the market by American companies, selling to a home market which accounts for 65 per cent of all sales in electronics. The most recent development in electronics to come into production—integrated circuits—is dominated even more completely by the United States. The American market represents 90 per cent of the total market for integrated circuits, and American companies hold 80 per cent of the much smaller British market. One company based in Britain, Associated Semi-conductor Manufacturers, owned two-thirds by Mullard Ltd and one-third by the

siderations than it is at present because of its involvement in the supply of fuel and other materials? There would be obvious economies of manpower, and there is no doubt that the authority's prestige would be a great help in the export trade—whatever that may be. Indeed, making the authority into the linch-pin of the reactor construction industry would merely extend to the British market the kind of arrangement which is often used elsewhere. But one result would be to decrease still further the ability of most of the commercial builders of reactors to stand on their own feet in the design of nuclear equipment. There is also a possibility that the intervention of the authority in this role is not essential, if only because one of the commercial organizations seems well equipped to win orders for itself (see page 213).

A decision on this important issue cannot in decency be made until the Select Committee on Science and Technology has published its recommendations on the nuclear energy industry, but this is in one sense a formality. The proceedings of the committee were as much a process of self-education as of searching inquiry, which means that there will be a natural temptation for the committee to choose one (or even several) of the different solutions proffered by the various witnesses. The difficulty, of course, is that prescriptions for prosperity provided by vested interests such as the Atomic Energy Authority and the Central Electricity Generating Board may depart in several important ways from the ideal. Of the radical solutions with a claim to be taken seriously, Lord Penney's own proposal deserves quite serious study. Many of the opposing arguments which must be weighed against each other are, however, subtle and even unfamiliar. Immediate gains could easily be outweighed by more distant disadvantages. This, then, is the point at which a wise decision is most of all essential. The whole future of the nuclear energy industry in Britain may depend on it. There is hardly any time to wait.

General Electric Company, is now making a determined attempt to increase its share of the market, both in Britain and in the United States.

Although Associated Semi-conductor Manufacturers has been producing transistors for some time, its entry into the integrated circuit market has been delayed. Integrated circuits can perform most electronic functions, although they are no bigger than a pin head. They are manufactured from single crystals of silicon, with successive layers of oxide and other materials which are diffused onto the surface. A slice of silicon 1.5 in. in diameter will accommodate as many as 600 circuits. Production requires rigorous control of the factory environment, and most of the operations at the Southampton factory of ASM are conducted in clean rooms.

So far, the use of microcircuits has been restricted to the more esoteric parts of industry and defence. The first important market to be won over will be in computers where microcircuits, even if they are not actually cheaper than transistors, offer cheaper design because fewer circuits are needed. The telecommunications field is likely to follow, although in Britain this will involve winning over the General Post Office, which is still wedded to conventional technology for most applications. After that, much wider markets may be opened, in radio, colour television and even motor cars. Much will depend on the price of integrated circuits—their reliability is already proved. But price is falling rapidly, from about £1.5 for each component a year ago, to £1 each today, and perhaps £0.5 each next year. Apart from the understandable desire of manufacturers to encourage the use of microcircuits, it is also the case that the productive capacity already in operation is far greater than present demand justifies. There may therefore be an element of dumping in the rapid decrease in prices, as a discouragement to other firms to enter the field. As the price falls and technology advances, it becomes increasingly hard for new entrants to the industry to justify their capital expenditure. Companies now planning an investment in microcircuitry, for instance, would probably do better to forget it.

A very large investment has been made in the Southampton factory of ASM; £4 million has already been spent, and another £11 million is to come. The result is the largest semi-conductor and integrated

First AGR for Scotland

THE Nuclear Power Group last week won the contract for Hunterston B nuclear power station. The contract, which was awarded by the South of Scotland Electricity Board, is for a 1,250 MW(e) station to be sited next to Hunterston A, which is a 300 MW Magnox station. SSEB will be paying £87.5 million for the station, and in addition will have to pay the initial fuel charges. The price announced shows only a modest reduction from the price for Hinkley Point B, which was negotiated between TNPG and the Central Electricity Generating Board. TNPG says that the price for Hinkley Point B at the corresponding stage was £90 million.

It is hard to see how this tallies with the information given to the Select Committee on Science and Technology by Mr S. A. Ghalib, managing director of the Nuclear Power Group. Mr Ghalib explained that for direct replication of a design, a cost reduction of 10 per cent could be expected. For a development of the design, he went on, even greater savings could be achieved, and he quoted the difference between the Dungeness B contract, awarded to Atomic Power Constructions, and Hinkley Point B. If Hunterston B is to be a direct copy of Hinkley B, the SSEB should therefore have been expecting a tender of about £81 million; if it is not a direct copy, but a development, then by Mr Ghalib's argument the price should have been even less. Both stations are the same size and type; Hinkley will come into operation in 1972, and Hunterston in 1973.

The contract also makes Colonel O. W. Raby's remarks to the Select Committee look a little ill-judged. Colonel Raby, who is managing director of Atomic Power Constructions Ltd, claimed that his

circuit factory in Europe, built, ASM hopes, just in time for the boom in microcircuitry which it believes is on the horizon. Although the market is worth only £5 million in Britain this year, ASM believes it will be worth £20 million by 1970 and £50 million in 1975. Already the market in the United States is worth \$200 million, and ASM hopes to break into it through agreements between Westinghouse and Philips (the parent company of Mullard). Particular emphasis is being placed in the development of exceedingly fast digital circuits. Dr F. E. Jones, managing director of Mullard, stresses how difficult it is to attack the American market-first, it is necessary to obtain type approval from an American manufacturer and then it is necessary to bypass the Buy America Act, which discriminates in favour of the home producer.

Would a reorganization of the British electronics industry help British companies to become competitive? Mr Ronald Grierson of the Industrial Reorganization Corporation certainly believes so, and favours a merger which would produce two companies in the microcircuitry field. ASM has had talks with the IRC, and is now waiting for a review of the industry which IRC is producing. Not all is going IRC's way at the moment, however, and the take-over bid by GEC for Associated Electrical Industries is turning into a real battle. What seems logical to outsiders may not always be agreeable to those in the industry.

consortium could have undercut TNPG on the Hinkley contract if it had been allowed to tender. Despite this claim, APC has failed to win the Hunterston contract. There may be special difficulties in the Hunterston contract which have increased the price, but neither TNPG or SSEB has yet indicated any.

The contract leaves Nuclear Design and Construction, Ltd, the third consortium, very much out in the cold. Without an order for three years, NDC must now be favourites for the role of odd man out if the number of consortia is reduced to two. There are now talks of an amalgamation between APC and NDC, but both consortia claim that the Hunterston contract has nothing to do with it.

The end product seems likely to be that Scotland will generate electricity only marginally more cheaply than is possible at Hinkley Point B. The Hinkley price is quoted as 0.476d. per kWh; assuming that fuel and site costs are comparable at Hunterston, generation costs would be almost identical. This must be a very tentative conclusion, however, since both SSEB and TNPG are uncommunicative about exact costs. Both will be earnestly hoping that the price increases which have been a feature of the Dungeness B contract will not repeat themselves at Hunterston. At least the Hunterston design will incorporate proved design features, so it may be possible to avoid escalation. The station will have two reactors enclosed in prestressed concrete vessels with integral boilers and gas circulation. This design has already been used by TNPG at the Oldbury Magnox station which comes into operation late this year. Each reactor at Hunterston will supply steam at conventional temperature and pressure to a 660 MW turbo-alternator. The reactor will use enriched uranium in the form of uranium dioxide, and the design provides for the reactor to be refuelled on power by a single charge machine. Work will begin on the Hunterston site immediately.

The Nuclear Power Group is now in the happy position of having won contracts for at least £180 million worth of work. Power stations built by the group have generated a quarter of the world's nuclear electricity, and the group has the unique distinction of having successfully exported British nuclear technology, in the building of the Latina 200 MW station in Italy. (The other British export was to Japan, and is better not mentioned.) The group is bound to regard this latest order as a guarantee that it will still be in business after the Select Committee on Science and Technology publishes its report on the British nuclear power industry at the end of this month.

Redeploying Scientists

A TRENCHANT defence of the British Government's interventionist policy towards industry was given by Mr Anthony Wedgwood Benn, Minister of Technology, when he spoke at Imperial College on October 17. Mr Benn at first seemed eager to show how unexceptional intervention in Britain is—"The great military—industrial complex in the United States," he pointed out, "constitutes a public sector of formidable proportions which makes even the most radical British interventionist look like an amateur."

Despite its mildness, however, government intervention was inevitable and essential. In the computer industry, the ministry and NRDC had made available substantial amounts of money, and the next stage of the ministry's policy towards computers would concentrate on applications. Mr Benn hesitated to say where the British computer industry would have been without government support. The ministry's policy towards shipbuilding was openly interventionist, and the aid made possible by the setting up of the Shipbuilding Industry Board would only be made available to yards that would toe the government line by reorganizing or regrouping. In nuclear power, the task of finding the right industrial structure to allow Britain to cash in on the tremendous investment in civil research and development was almost a classic. Mr Benn gave away little of the Government's attitude towards the Atomic Energy Authority, merely observing that, having solved many of the technical problems it had set out to solve, it now faced some unresolved choices about its future.

Mr Benn did say something about his attitude towards the Government research establishments. There were two approaches, he thought; one would be to group the establishments under some sort of Technological Authority working closely with industry, and identifying and pursuing goals less expensive and more relevant than the US space programme but capable of establishing a tradition of excellence. would simply be to say that the establishments had outlived their usefulness, and run them down sharply, closing many in the process. But neither of these approaches would in fact be adopted-instead the ministry intended to pursue a carefully phased programme designed to break down the barriers separating research from production. The integration of research and production had proved to be the secret of industrial success abroad, Mr Benn thought, and it must become a major policy objective in Britain, too. "It would be quite wrong to find work inside Government establishments for its own sake just to keep scientists and engineers employed."

This aim might involve Government laboratories undertaking contract research from industrial firms on a basis of confidentiality. Alternatively, intimate connexions might be developed between establishments and the new large firms which will emerge—the Gas Turbine Establishment at Pyestock and Rolls Royce was an obvious example of this approach. Finally, the ministry would try to make it easier for people to move between the establishments and industry. "What we are engaged on is not just an attempt to transfer the emphasis from defence to civil work-although we are doing that—nor even to change the emphasis between intra-mural and extra-mural—though we shall do that as well, but to secure a re-distribution of more of our qualified scientists and engineers from research, wherever it is done, into design development production, marketing, and above all management.'

More Money for Innovation

THE National Research Development Corporation is learning to live with wealth. Three years ago its borrowing powers were limited to £10 million; they were then increased to £25 million, and a few months ago to £50 million. Last week the Minister of Technology was talking of increasing them yet again. But all this has not gone to the corporation's head, as its annual report for 1966–67 shows. It is the mixture as before—the development of inventions from industry, universities and government laboratories, with a liberal sprinkling of ideas from private inventors, some amusing, some improbable and some downright eccentric. What, for instance, is one to make of a semi-automatic jelly tester?

Increasingly, though, the corporation is becoming involved in industry's own problems, which call for commercial as well as technical judgments. This year 69 new projects have been taken on, against 28 for the 9 months covered by the last report, and the expenditure on development projects is up, to £3.65 million. Exploitation receipts are also up, from £430,000 to £793,000, and the total income is £1,307,000, against total outgoings of £4,705,000. As well as the 69 new projects taken on, support was continued for 115 existing projects. The corporation seems so far to have produced only one real money spinner-perhaps surprisingly it comes from the Medical Research Council and the University of Oxford. It is cephalosporin C, the antibiotic which the corporation has supported since 1952. Of the total income of the corporation, £493,000 came from overseas, and cephalosporin accounted for two-thirds of this. The corporation should be grateful to Professor Abraham and Dr Newton of the Sir William Dunn School of Pathology at Oxford, who discovered and isolated cephalosporin. The corporation continued to support the development of hovercraft, and records with pleasure that a patent dispute in the United States was resolved in favour of Mr Christopher Cockerell, the British inventor of the hovercraft.

There is one new idea in this year's report. The corporation is supporting a project which enables a

firm to install mechanically controlled machine tools and operate them for a period on approval. This project, the report points out, was undertaken at the specific request of the Ministry of Technology. Other new projects include plastic sacks for tropical produce, a new tower fermentation process, and transducer production, in collaboration with George Kent Ltd, for measuring instruments for the process control industry. That project, too, has the stamp of the Ministry of Technology. The corporation is also helping to develop microfilm equipment, and a high torque motor developed at International Research and Development in Newcastle upon Tyne. Although the report does not say so, it would be fair to guess that the motor makes use of superconducting magnets to produce a high torque at low speeds.

Promotion without Obligation

More scientists working in Government establishments in Britain have been awarded "special merit" promotions. These promotions, awarded to scientists who have produced a very high standard of original work, enable them to continue their research work without the administrative responsibility normally associated with their new grades. The promotions follow recommendations by a special committee which each year reviews the work of scientists doing research in Government and other public service establishments.

Of the twenty-six research workers awarded promotions this year, Mr K. C. Bowen, Dr J. Croney, Dr C. Hilsun, Dr O. Kubaschewski and Dr E. H. Mansfield have been promoted to Deputy Chief Scientific Officer. Dr G. H. Byford, Dr P. Dean, Dr A. Franks, Dr H. A. French. Dr P. H. Greenwood, Mr H. V. Hempleman, Dr J. M. Linke, Dr E. G. S. Paige, Mr P. H. Parkin, Dr E. R. Pike, Mr W. J. G. Pinsker and Mr D. E. Weston have become Senior Principal Scientific Officers and Dr J. H. Darbyshire is now a Senior Research Officer, Grade I. A number of promotions have also been made within the United Kingdom Atomic Energy Authority. Thus Dr P. G. Burke and Dr R. J. N. Phillips have become Senior Scientific Officers. In the Agricultural Research Council, Dr L. W. Mapson has been promoted to Deputy Chief Scientific Officer. Dr J. Bligh, Dr P. N. Hobson, Dr Daphne J. Osborne, Dr F. W. Robertson and Dr C. R. W. Spedding are now designated Senior Principal Scientific Officers.

Sad Gas

FOR an industry which has just found unexpected new wealth on its doorstep, the British gas industry is singularly long-faced. The annual report of the Gas Council (HMSO, 16s. 6d.) reveals that this year's surplus has fallen sharply from £11·1 million last year to only £3·9 million this year. In the days before natural gas was found beneath the North Sea, the council did much better—in 1964–65, profits were as high as £15·2 million. This year's results mean that the council has failed to maintain its running target of a return of 10·2 per cent on capital invested; the figure now stands at 9·1 per cent.

In fact these depressing results are understandable. The need for extensive re-equipment to cater for natural gas has combined with economic conditions to give the Gas Council a tricky year. Transitional costs have not yet justified themselves in increased revenue, and the Government-imposed standstill on prices has aggravated the situation. The council is now discussing with the Ministry of Power what its financial objectives should be over the next few years, and the report points out that future financial objectives must strike a balance between the transitional burdens in the short term and the undoubted benefits in the long term.

Research, testing and development cost £2.65 million in 1966–67, the report reveals, and the area gas boards spent a further £1.26 million on development. The basic research group has been working on catalysis, adsorption and chemisorption and reaction kinetics. The conversion to natural gas has involved the development of a natural gas substitute which can be burned in the same burners during the period of conversion and for peak loads later. Several underground storage sites have been investigated for porosity, permeability and pore-size distribution, and attempts are being made to assess the risk of contamination of gas held underground by hydrogen sulphide of bacterial origin.

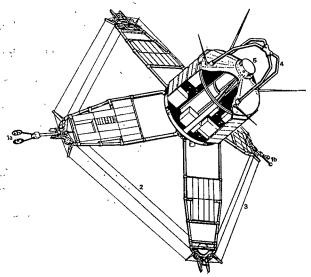

Snags in Space

ARIEL III, the first all-British satellite, has been a mixed success. Although all the sub-systems—power, data handling and telemetry—have worked well and show every sign of fulfilling their design life of one year, the data they have been sending back have been confused. One experiment, from the Nuffield Radio Astronomy Laboratory at Jodrell Bank, has so far yielded only interference.

There seems no doubt that the two experiments designed at the University of Birmingham are the cause of the interference. One measures electron density in space by means of a parallel plate capacitor consisting of two circular grids carried at the end of one of the solar cell paddles, and the other, attached to another paddle, measures electron temperature. Both these experiments are working well, according to Dr J. H. Wager of the University of Birmingham, who described them at a symposium organized by the Institution of Electronic and Radio Engineers on October 13. Unfortunately, both experiments interfere with the Jodrell Bank experiment, which is designed to measure absolute values of cosmic noise in Dr P. C. Gregory from Jodrell Bank has identified two distinct types of interference, one caused by the density probe and the other by the temperature probe. The first type is the more severe, saturating receiver output under all conditions, but the second is not quite so severe, and Dr Gregory philosophically hopes for at least some results from his experiment.

The Birmingham experiments have also upset the attempt by the Meteorological Office to measure the concentration of molecular oxygen in space. Dr P. J. L. Wildman described the experiment, in which the attenuation of the light of the Sun is studied as the satellite enters and leaves the Earth's shadow. In addition to the Birmingham interference, which in this case is not too severe, the experiment is sending back a spurious signal from the shadow side of the Earth, when it should be silent.

Professor Sayers from Birmingham is unrepentant. Other experimenters, he said at the symposium, paid too little attention to the problem of integrating their experiments into the satellite. Only the University of Sheffield was worried about possible interference from Birmingham; as a result, changes were made, and the Sheffield experiment has worked perfectly.

ARIEL III SATELLITE. 1, University of Birmingham: (a) electron density sensor; (b) electron temperature sensor. 2, University of Sheffield: VLIF loop antennae. 3, University of Manchester (Jodrell Bank): galactic noise loop antenna. 4, Radie and Space Research Station: terrestrial noise loop antennae. 5, Meteorological Office: oxygen distribution scanning mirror.

In all probability the interference could not have been predicted, except by testing the satellite with all experiments going in an ionized gas, a facility not available. A much simpler solution would have been to provide switching so that all the experiments could be turned on and off, instead of all operating all the time. NASA, which launched Ariel III for the Science Research Council, advised against this, because it increases complexity and all-up weight (Ariel III was already 25 per cent heavier than the target weight). Professor Sayers, however, believes that it would have been quite easy to switch off his experiment without increasing the number of commands. This is not the first time that interference of this sort has occurred, and clearly it would be convenient if experiments could be switched on and off. The British Black Arrow launcher should be able to offer more commands, space scientists hope.

Waiting for Answers

ALTHOUGH the Austrian Government has now declared its willingness to participate in the construction of the 300 GeV proton accelerator to be built within CERN, there is as yet no sign that the potentially important contributors to the cost of the project will make up their minds before the next meeting of the council of CERN, due to take place in Geneva on December 14. The British answer to the request by CERN for promises of contributions from the thirteen members of the organization is likely to come late in the day. Arrangements have apparently been made for a period of consultations within the Government, and it is unlikely that these will be completed much in advance of the timetable laid down by CERN. At the last

meeting of the CERN council at the end of September, the British delegation raised the problem of how to modify the draft convention for the construction of the 300 GeV machine in such a way that it would not be possible for countries making small contributions to the cost of the new machine to force an unwanted escalation of cost on the big subscribers. In the original version of the convention, as in the conventions which regulate the operation of the Meyrin Laboratory and of the proton storage rings which accompany it, the principle of one country one vote has been adopted. The British view that this might lead to irresponsible decisions in certain circumstances seems to have been accepted as an honest attempt to solve a common problem.

British fear of an escalation of cost seems to be shared by other European countries. At the last council meeting, the British delegation appears to have emphasized that its proposed contribution to the new CERN machine, estimated to amount to £37.5 million in the next ten years, is a substantial part of the annual budget of the Science Research Council. In circumstances like that, the argument goes, escalation would take funds from other fields of science and would for that reason be intolerable. So far, Belgium has agreed to participate, even on the original basis. So now has Austria. In spite of vigorous protestations of support by scientists among the French delegation to the CERN conference, however, there has so far been no official statement by the French authorities.

The eagerness the planners have shown has, however, been strengthened by reports of the speed with which the planning scheme under Professor R. Wilson for the 200 GeV machine being built in the United States is making progress. It is also now known that the proton accelerator at Serpukhov has been operated successfully to produce protons at an energy of 75 GeV. This is somewhat greater than the maximum design energy of 70 GeV, but, at the extreme energies reached in the past weeks of commissioning, the intensity of the beam has been such that each pulse has produced 10⁸ protons—one-thousandth of the number of protons in a pulse when the machine is operating successfully. Full operation cannot be long delayed. In spite of the agreement between CERN and the Soviet Union that will give European physicists access to the Russian machine, the news from Serpukhov will no doubt strengthen the sense of deprivation at Geneva.

European Physical Society

AGREEMENT has been reached on the formation of a European Physical Society and it is planned that there should be an inaugural meeting in Florence in the last week of September 1968. This will be a fitting tribute to the enthusiasm of the Italians for the new venture and, in particular, to that of Professor G. Bernardini, who is chairman of the steering committee. The draft constitution of the proposed society, which has already been circulated to the councils of national physical societies, is to be discussed and—no doubt—approved at a meeting of the steering committee due to take place early in 1968.

The view that the new society should begin as a loose federation will appeal not merely to those of

Gaulist temperament but also to those who are aware of the practical problems of integrating the physics community. One obvious obstacle is the variation in the character of physical societies from one country to another. Another is the obscurity of many of the organizations which should properly play a part in the development of an integrated society. No doubt it will be several years before the various member societies have enough experience of each other's needs and interests for them to know which parts of their activities can be integrated and which will have to be kept going on a national basis. Until then, however, the organizers of the society see plenty of scope for constructive and common activity, principally in the organization of meetings. It will be interesting to see whether there are funds for financing exchange visits on a significant scale. The problems of journals have not apparently been tackled yet, although there seems to be a view that the ideal solution would be the specialization of existing journals in certain fields of physics. The official headquarters will probably be in Geneva.

New Trend in Teaching Science

Is it possible to teach children engineering? This was the common question asked at the Institute of Electrical Engineers on October 12, when Mr G. B. Harrison, head of the department of creative design at Loughborough College of Education, opened a discussion entitled "The Influences of Changes in School Curricula on the Intake of Engineering Courses".

Mr Harrison, who is also director of the Schools Council engineering project, began by outlining the aims of the council, which helps children to understand what technology has to offer and trains them to meet the needs of growing up in a society dominated by technology. According to Mr Harrison, if technology is indeed accepted in schools, the traditional academic attitude of teachers will have to give way to the preparation of new material, apparatus, films, programmes and books that could be discarded when obsolete. He applauded the introduction of engineering as an A-level subject by five of the eight examining boards in the country, but is afraid that diversity might lead to confusion. A common A-level paper is essential so that universities, technical colleges and industry know what is being done at the schools.

An engineering science paper has been introduced by the Northern Universities Joint Matriculation Board to provide an alternative to physics which would meet university requirements. Although the syllabus is similar to traditional physics, it does include project work and practical exercises which demand design ability and creativity. The Oxford Examination Board also has an engineering course. This is, however, to be taken in addition to maths and physics in order to broaden the candidate's horizon. It includes the philosophy of engineering, design aspects and project work. The Cambridge course is essentially mechanical design but also includes the theory of structures and project work. Marks are awarded for project work and added as a bonus to the A-level physics mark. The value of all these courses will depend on the extent to which university courses are geared to work at school. According to Mr Harrison, the present flow from school to university is a series of acute mis-matches that can only be remedied by a long term reappraisal of the whole educational system.

In view of the importance of the topic, the discussion was sparsely attended, but there were several interesting points raised. Who, for example, is going to teach engineering in schools? Certainly not the traditionally trained teachers who have passed through training college and who are often accused of being out of touch. Furthermore, as one speaker noted, this is not merely the age of technology, but of change in general: we are no longer living in a static society, and developments should be made in all directions without over-emphasizing any one particular aspect. There was general agreement that a new approach to education is needed and that the attitude of universities and technical colleges towards the acceptance of engineering as an A-level subject should be made Obviously there are many arguments for and against the scheme, but several questions have yet to be answered. For example, have university students benefited by taking engineering at school? What evidence is there that children want technology and engineering in their general syllabus; have headmasters been approached by pupils anxious to study the additional subjects? Perhaps most important of all, has the introduction of engineering in the sixth form been reflected in the numbers reading engineering at establishments of further education? have a census of opinion at all major schools to take into consideration the views of children themselves? All this may be clarified by the working paper, prepared by the Schools Council, which is shortly to be distributed.

Indian Spoken Here

THE proposed change of language in Indian education away from English prompted Mr Chagla, the Foreign Secretary, to resign early in September. The following week the proposal was discussed at the Conference of Vice-Chancellors in New Delhi, and although the resulting statement published afterwards is in agreement, it contains a certain amount of qualification.

The intention is that English should cease to be the centre of the higher education system, but its importance as a tool is not underestimated. School teaching is at present carried out in regional languages and it is hoped to extend this to undergraduate level. It is realized that a link language is essential, and that the need for a foreign language increases year by year, particularly for library study. Postgraduate courses will continue to be based on English, as translation of books and journals at this level would be impossibly expensive. Regional universities could work on this basis, but all-India institutions raise another problem. Hindi is at present spoken by 40 per cent of the Indian population, but there are some states that are actively against it. Any decision to use it as the education medium in national establishments would therefore have to be made with agreement from non-Hindi states. It is also realized that in multi-lingual cities English may have to be retained as the education medium, alongside the regional languages. The speed and nature of the changes are expected to vary from one university to another, according to circumstances. but undergraduate courses should not take more than 10 years to be adapted.

The conference approved these proposals, and placed particular emphasis on its endorsement of the statement by the education minister that the criterion for any change-over decision should be an improvement in standards.

Broadcasting Abroad

LARGELY at the initiative of the Ford Foundation, plans are being canvassed for the setting up of an International Broadcasting Institute intended to ensure that the fullest use is made of technical innovations such as Earth satellites. The institute has a distinguished backing, with sponsors such as Dr J. Wiesner in the United States, and Mr Kenneth Younger and Professor Asa Briggs in the United Kingdom. A draft constitution is now circulating, and was indeed discussed in detail at a meeting in New York two weeks ago. The immediate problem is to find financial support for the enterprise, and several foundations have already been approached. To begin with, the institute might consist of a director supported by a small office staff and with a brief to define the field in which a more fully equipped institute might operate. For several reasons, one of which is that non-profit organizations are well treated by the taxation authorities in the United Kingdom, the official headquarters of the institute are likely to be in London.

For the time being, at least, the nucleus of the new institute thinks of itself more as a research organization than a pressure group. It would tackle a variety of problems, such as the way in which broadcasting (principally of television) might be used to provide educational services for developing countries and the legal questions which might arise in broadcasting from one country to another, possibly by means of satellites. Whether the institute would try to engage directly in the issue of just how the new international agreement for INTELSAT should be negotiated is another problem. It also remains to be seen how the institute will be able to define its relationships with bodies, official and otherwise, already operating in this field. Broadcasting networks in Britain and the United States seem to be cool but not hostile.

Social Medicine

THE only research unit of the Medical Research Council devoted to social medicine is just settling down in its new quarters at the London School of Hygiene and Tropical Medicine. Professor J. N. Morris, formerly the director, becomes honorary director of the unit on his appointment to the chair of public health in the University of London. The unit, consisting of a staff of eleven doctors, statisticians and social scientists as well as clerical staff, moves with him.

Three main topics are being investigated by the unit, which is using the same general methods of statistical analysis, individual and clinical studies for each. Heart disease, particularly coronary thrombosis, has been under examination for about twenty years, with three aims in view: first to discover causes, secondly to find individuals who might be particularly susceptible, and finally to attempt to reduce the risks for these individuals. Using the discovery that high cholesterol levels in the blood point to thrombosis, experiments are being carried out to see if lowering

these lipid levels in the blood reduces the incidence of thrombosis among otherwise healthy people. Trial groups in Edinburgh, Prague and Budapest are cooperating in this project. A study is about to be made of men in the civil service to see what effects exercise may have on the incidence of thrombosis. The unit has already established that occupational exercise has a protective value.

In its former home in the East End of London the unit involved itself in local affairs by beginning a survey of juvenile delinquency in that area. No obvious conclusions could be drawn from variations in housing backgrounds, and apparently similar schools produced widely differing delinquency rates. Attitudes within the schools may play an important part, but have yet to be studied. It is hoped that statistical and clinical analyses will lead eventually to a reasonably simple test that can be used by magistrates and probation officers to discover the likelihood of a first offender becoming one of the hard core of delinquents.

Operational research into various aspects of the Health Service forms the third activity of the unit. At present the quality and effectiveness of medical care in different types of hospital are being assessed. Why is it, for example, that teaching hospitals are more effective than others? In this field of everyday medicine it is important to discover causes for variations in the success rates, and a large scale survey of prostate treatment is now being made.

Connective Tissue Clubs Connected

AT the joint meeting of the French and British micropolysaccharide clubs, held on September 29 at the Institut Pasteur, Dr Robert, the secretary of the French club which initiated this first joint international meeting, proposed that a European Federation of Connective Tissue Clubs should be formed. This was agreed; Professor Kuhn of Munich pledged West German Under the federation the existing participation. national clubs will of course retain their identity and local interests, as well as participate in international meetings. This arrangement should improve on the present situation in which European workers meet each other, if at all, as visitors in the USA. Discussions are now under way in the hope that the return Anglo-French meeting in 1968, to be held in Britain, will be the first full meeting of the new federation.

At the Paris meeting the magnificent hospitality of Professor Delaunay and the French club provided a perfect background for much productive discussion. Seventeen communications, two of them full lectures by Dr J. T. Dingle and Professor J. Montreuil, were given during the day, on the chemistry, metabolism, morphology, embryology and pathology of connective tissue and its components.

The federation, by arranging regular international meetings, should provide new impetus for the European biochemists, pathologists, electron microscopists and many others involved in the expanding field of connective tissue research.

Human Physiology

THE National Institute for Medical Research seems particularly anxious to make known its work on the

physiology of normal man and the application of its results in industry and the services. A number of interesting and varied projects are currently in progress at the laboratories. In the Department of Human Biomechanics, for example, R. J. Whitney is studying movements of normal people. Photography is used for an exact analysis of the motion of different parts of the body, and the presence or absence of activity in specific muscles which may be involved in the motion is registered by electromyography. One experiment, completed nine months ago, was concerned with the effects of prohibition of movement on physiological and psychological activities of man. Several subjects under thirty were examined in four types of sitting positions varying from supine to upright during twenty-four hours of confinement. Among the changes recorded were EMG of limbs, heart pulse and posture change. A time lapse film indicated that principal movement of the head and feet occurred during the twenty-four hours. Although the results are difficult to analyse, there is evidence of a definite diurnal rhythm in temperature and in swelling of the ankles.

The function of the Division of Biomedical Engineering is to establish a link between modern technology and human biology. It has designed SAMI (Socially Acceptable Monitoring Instrument) to investigate "normal man leading a normal life". This heart beat counter, which derives its input signal from two adhesive chest electrodes, can store acquired information for prolonged periods by means of a reversible electrochemical integrator. Using SAMI, emotional stress has been measured in airline pilots, pregnant women, Peruvian women and schoolchildren. SAMI can also be used to estimate human activity and in clinical follow-up and in work study. A temperature SAMI is also becoming available and SAMIs for noise and posture are in preparation. The development of FAIR (Fast Access Information Retrieval) in the department should lead to full-text, special subject collections becoming available on a user's desk, together with a retrieval system which allows one to generate highly specific subject headings. By providing a list of key words for coding documents, it is hoped that a larger scientific population will consult literature sources of information.

Another interesting study at the laboratories is the investigation of anaemia during pregnancy in immigrant mothers with abnormal haemoglobins and thalassaemia. In the heterozygous conditions, these are both clinically mild but become more severe during increased physiological stress. The traits can be identified by starch-gel electrophoresis and treated with iron administered orally. In 1966 a Tristan da Cunha working party was set up through the council, to investigate the health of the islanders and to assess the balance of their diets. Results indicated that the islanders do not, in fact, live up to their reputation for good health.

Food Additives

THE use of food additives is difficult to control satisfactorily, for although many countries have agencies and scientific institutions with this special responsibility, others lack adequate facilities. The problem is being dealt with by a joint FAO/WHO programme which aims to make systematic evaluations of food

additives and to provide evidence to member states of FAO and WHO. The programme is implemented by the joint FAO/WHO Expert Committee on Food Additives which advises the Codex Committee on Food Additives, which in turn, through the Codex Alimentarius Commission, proposes to governments internationally acceptable tolerances for additives in various foods.

The Codex Committee selects the substances to be considered by the Expert Committee, whose terms of reference are to establish specifications for identity and purity for food additives and to evaluate toxicological data. It also recommends, if possible, acceptable daily intakes for man. This committee has just produced its tenth report, on "Some Emulsifiers and Stabilizers and Certain Other Substances" (WHO Technical Report Series, No. 373; 1967). The committee recommends that biochemical and metabolic studies be substituted sometimes for the more usual toxicological studies when the effects of food additives are evaluated. If the additive is completely broken down in normal metabolism to common dietary or body constituents, toxicological investigation is a wasted effort, for the additives are then behaving like foods. For such cases an acceptable daily intake has been calculated such that the additive should not increase the food component into which it is converted by more than about 5 per cent of the amount in an average diet. The fatty emulsifiers such as acetic, citric and lactic acid and fatty acid esters of glycerol are in this category, for in metabolism they are all hydrolysed to acceptable dietary constituents.

The committee says that toxic concentrations of arsenic, lead or heavy metals are unlikely to be found in food now, but it gives specifications to encourage the use of good quality raw materials and equipment. Most normal diets probably supply 1.5–2.0 mg of arsenic each day. The committee puts the maximum acceptable load at 0.05 mg/kg of body weight, and recommends that the maximum content of arsenic in food additives be 3 mg/kg; for heavy metals they recommend 40 mg/kg, and for lead 10 mg/kg in cases where the daily intake of the additive exceeds 1 g.

In several cases a decision on the use of an additive has had to be deferred because of lack of data. Of the natural stabilizers, furcelleran and its salts could not be evaluated in the absence of toxicological data. Concerning carrageen and its salts, now used as food additives, toxicological data are inadequate to establish an acceptable daily intake, and the committee recommends that this information be made available within the next four years so that a decision may be taken on permission to continue the use of this substance. Information is also inadequate concerning those long established additives gum arabic, karaya, tragacanth and carob bean gum, although tentative specifications have been prepared. Details of all specifications will be given in monographs containing biological data and toxicological evaluation of the various additives, and the committee suggests that a decision to use a particular additive should only be taken after consulting the detailed monographs.

Making Air Fresh

"TAKE a deep breath and be sick" is a wry comment sometimes heard in the United States. In Britain,

the National Society for Clean Air is trying to forestall such cynicism. The annual conference of the society is being held in Blackpool this week, and papers on various aspects of air pollution are being presented. The work of the society was described by Sir John Charrington in his presidential address on Tuesday. Sir John described the change of emphasis from industrial smoke to vehicle pollution and called for amendments to the Clean Air Act.

Air pollution from road vehicles was the subject of the report of the technical committee which was presented by Dr Albert Parker. Carbon monoxide is the principal pollutant in exhausts, although nitrogen oxides and smoke also occur. In Britain less than one-third of atmospheric carbon monoxide comes at present from vehicles, but if present rates of increase continue the amount discharged will have doubled by 1980 to more than 10 million tons a year. danger from carbon monoxide arises particularly in traffic jams, when there is little chance of dispersion. Fifty p.p.m. is the maximum concentration of carbon monoxide allowed for an eight hour day in industry, and yet in Oxford Street recently 360 p.p.m. was measured. There is as yet no legislation in Britain for controlling emission from petrol engine vehicles, and the British Standard Specification for diesel engines is above the present emission level set by most manufacturers. Work continues, however, on modifications to petrol engine design, for if it is ensured that all fuel is burnt, there will be little poisonous exhaust. Recirculation of crankcase fumes helps, and fuel injection systems and modified carburettors have been installed in some cars. The initial cost of the vehicle is increased, but fuel consumption is improved. It is hoped that preliminary murmurs from the Ministry of Transport on this subject will soon be transformed into effective schemes for checks and controls.

Industries using dangerous materials can keep checks on their employees, but waste substances that escape into the surrounding countryside can have serious effects. In a paper presented on Tuesday, beryllium, asbestos and fluorides were discussed. Illness and death can occur in both animals and humans living near processing plants, or from contact with industrial workers and their belongings, but no suggestions were made for improving the situation. The paper ended with a commendation of the care taken by those responsible for controls on radioactive waste.

By contrast, Dr E. F. Schumacher, economic adviser to the National Coal Board, considered the dangers of radioactive pollution. Too often these days decisions are based solely on economic considerations, with little reference to environmental factors. Pollution of the atmosphere by radioactive substances for the sake of cheaper electricity was the example Dr Schumacher used in his Des Voeux memorial lecture, when he related economics to clean air problems.

And so to the domestic scene, where keeping the home fires burning produces an estimated £280 million worth of damage every year. Working on an average figure of £16 for conversion to smokeless heating, the capital cost for cleaning up the black areas of England once and for all would come to £100 million. In giving these figures, Mr A. D. Smith described the situation as economically and technically crazy, because pollution from domestic smoke is the easiest

type to remove. If a date could be set when Treasury grants for conversion would be stopped, people might jump to get their money while they can.

Worthy Cause

This month, Mr Peter Scott will launch an appeal for £75,000 for development at Wicken Fen—the remnant of the once great fens of Cambridgeshire. Wicken Fen reserve, one of the oldest and most famous nature reserves in Britain, is approximately 700 acres in extent and has long been the site of biological and nature studies. But in recent years there has been a great increase in the use of the area by members of the general public, school parties and groups of students. To encourage these activities while at the same time conserving vegetation and wild life, the Wicken Fen Local Committee of the National Trust has made two sensible proposals. One, following the American National Parks pattern, is the erection of an open air laboratory with associated museum, lecture room and display unit and the provision of picnic and other facilities for visitors. A resident warden naturalist, appointed by the committee, will be in charge of the laboratory, but there will not be a permanent staff. Laboratory facilities, including exhibits and maps, will be available to interested parties, and school children will be allowed to examine in the laboratory their specimens at the end of a day's collecting. The other proposal is to create a marshland reserve in which a new range of aquatic and marsh communities can become established and provide a valuable habitat and migration refuge for many species of birds.

There has already been considerable progress in the management and conservation of the reserve. A ten acre mere, opened in 1955, is now the haunt of thousands of birds. A sixty acre reed field has also been established on the fen and, in the past three years, more than a mile of dyke has been cleared out. More manpower and modern implements are needed, however, to clear choked ditches and the wilderness of bushes—the result of years of financial difficulties. The present income of the fen, entirely composed of voluntary subscriptions and donations, is quite inadequate to meet these urgent needs.

The cause is particularly worthy. Instead of trying to restrict use of the reserve, the committee wishes to encourage public interest, while at the same time safeguarding the area.

Urban Grove for Academe

from Brenda Maddox

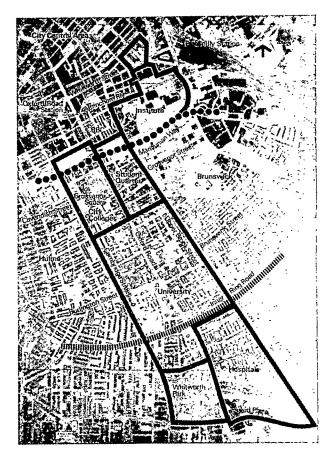

MANCHESTER is in the throes of a strenuous attempt to transform its academic community. The City Council, the University, the Institute of Science and Technology and the city's various colleges and hospitals are collaborating to create a green "educational precinct" in an area now engulfed by smog, traffic and slum. By 1984 the results of their efforts should be in place. There will be a strip, one and a quarter miles long and one-third of a mile wide, with the beautifully black university at its centre. Green grass and elevated pedestrian walkways will sweep from the site of the United Manchester Hospitals on the south to the group of city colleges on the north, and then east to take in

the Institute of Science and Technology. Cars, in the best modern manner, will be parked on the fringes, and new residential buildings will not only invite students into town, away from their suburban digs, but will screen the precinct from the noise of traffic.

The project may be what its planners (Hugh Wilson and Lewis Womersley) claim that it is: an opportunity unequalled in any city in Europe. Certainly the design critics are excited by it. The plan is grounded in realism and flexibility; it is considered to be a framework, not a master plan, the area being too large and susceptible to change for any kind of architectural uniformity to be stamped upon it. The raw material is planning.

What will create the precinct is the patterning of roads and grass and the mixture of different kinds of buildings-residence halls, academic departments, shops, restaurants and churches. The shape of any particular building is not crucial, although the planners insist on certain conformity from architects in building materials and in scale. (The centrepiece of the precinct -the university's new mathematics building—is being designed by the planners themselves.) The unifying element will be Mr Womersley's trademark, displayed before in his work in Sheffield and Nottingham—the first-floor footpath. People arriving at the precinct by bus—and there is little reason to hope that commuting will not continue to be a major characteristic of the Manchester academic scene—may take an escalator up to the walkways from the bus stop and continue, at first floor level, for the entire trip to their destination.

Will the precinct be beautiful ?—a burning question in such a renowned ugly spot as Manchester. answer, alas, is probably not. There is too much against The admirable realism behind the whole plan demands living with such obstacles as the Mancunian Way, the highway on stilts which, hardly finished, pours noise and darkness right across the heart of the precinct site. It isolates the university from the institute and the city colleges, creating a physical barrier to replace the invisible one which the precinct is supposed to eradicate. The whole scheme, however, depends really on the determination of the Manchester City Council to make the city more humane and attractive, even if it means sacrificing rateable land. This is a rare enough quality in city governments; one can hardly criticize the council for not wanting to tear down the Mancunian Way before it has barely risen. But the fact remains that this prior plan has doomed from the start any hope the precinct might have had of beauty and grandeur. The same, on a lesser scale, may be said of two city housing developments-

Brunswick and Hulme—which stand solidly on either side of the narrow strip. And, in an ideal world, the planners would have been able to remove Oxford Road, the north—south artery, altogether. As it must remain to carry buses and lorries, one wonders how successful Mr Womersley's pedestrian walkway will be in persuading people to walk up in the air. There is a danger that it will simply create more darkness at noon in a city which has more than its share.

That having been said, the precinct still looks like doing a lot for Manchester. It will draw the city and the university closer together; so should it make the city colleges, the adult education college and the medical school have a richer intellectual life because of association with the university and institute. If all goes according to plan, the precinct will be lively in the evening as well as during the day; it will be good for book-browsing and pram-pushing as well as for getting a degree.

NEWS AND VIEWS

Hallucinations to Order

ONE of the most alarming features of the drug LSD is that it can be made in the laboratory. In other words, there is no natural physical limitation of the scale on which, in suitably bizarre circumstances, it could be supplied to the public. It follows that those who are concerned to see that the use of drugs is controlled by legislation are at least a little nonplussed by the appearance of synthetic processes for manufacturing drugs which were originally derived from natural sources and, more especially, by the application of synthetic processes to the design of new drugs. Although it will be a long time before the flower children and their like would be able to synthesize their own psychomimetic agents, it is entirely proper that there should now be considerable anxiety about problems of control.

The report by Smythies et al. (Nature, 216, 128; 1967) is a reminder of the difficulty of controlling the use of drugs which can be synthesized, if only because it shows that several derivatives of amphetamine have properties which are similar in a number of ways to those of the frankly hallucinogenic drugs-LSD and mescaline, for example. Although there is, of course, no prospect that any of these materials will be put on public sale, the sheer diversity of them is startling, to say the least of it. The preliminary report of the properties of paramethoxyamphetamine is particularly arresting. In rats, this material seems to produce signs of behavioural disturbance which are similar to those produced by LSD at a dose of 3.1 mg per kg. With a dose merely twice as great, however, profound changes in the behaviour of the rats seem to have been brought about. One rat died after a day without recovering its normal state. In another, the severe disturbance persisted unchanged for a week, when that rat also died. In other words, it looks as if the preliminary studies with rats suggest that sufficiently large doses can have irreversible effects. Making an objective assessment of how paramethoxyamphetamine affects the behaviour of human beings will be difficult enough. But it is also plain that if the uncontrolled use of LSD is dangerous, other materials may bring even greater risks.

It would, however, be unfortunate if the particular properties of one material were to obscure the wider interest of what Smythies et al. have done. Their immediate objective has been to assess the potency of several derivatives of amphetamine, which pharmacologists know to be a stimulant of the central nervous system and which others know as a "pep pill". It has been known for more than a decade that derivatives of amphetamine can sometimes be similar in their effects to the more familiar drugs which produce hallucinations, and this is not surprising. After all, mescaline is

derived from phenylethylamine while amphetamine itself is phenylisopropylamine. One of the generalizations which has come out of the work which Smythies et al. have done is that a paramethoxy-group seems to be necessary for hallucinogenic activity. This in itself is suggestive of how hallucinogenic drugs may function.

But how? Smythies and his colleagues have put forward at least two suggestions as to how paramethoxyamphetamine may function. They suggest, for example, that it may interfere with the activity of an enzyme which is usually responsible for sweeping nervous tissue clear of the catecholamines which serve as means of communication with nerve cells of certain kinds. Another possibility is that the presence of a methoxy-group in the para position may interfere with the biochemical processes which are able to get rid of unsubstituted materials such as amphetamine. Evidently there is plenty for the biochemists to do, and there will probably now be several attempts at a detailed study of the interactions between the hallucinogenic drugs and the various enzyme systems to be found in nervous tissues. The signs are, however, that this will be a back-breaking job. The detailed biochemistry of drug action seems most often to be frustrated by difficulties which are not yet fully understood. Nobody will be surprised if a detailed understanding of the way in which hallucinogenic drugs function has to wait on a description and understanding in molecular terms of the structures in nerve cells which function as receptors for the molecules which carry information between nerve cells.

There also remains the possibility of a connexion between the activity of the hallucinogenic drugs and the causation of mental disturbances, including schizophrenia. Such a possibility has been on the cards ever since it seemed as if the substance in the urine of schizophrenic patients producing a "pink spot" on chromatography might be a derivative of phenylethylamine and thus closely related to mescaline. Smythies et al. point out that the likelihood of a link between hallucinogenic drugs and schizophrenia may be even greater now that it seems more probable that the pink spot is really paratyramine—itself a parahydroxylated compound. But this, of course, is frank speculation. The real value of the work now being reported is that it will help vividly to suggest ways in which the function not merely of specific drugs but of nervous tissue as well may be opened up to new enquiries. In the long run, it is just possible that there will be something to suggest how problems of drug dependence may be dealt with, which is some recompense to those who will regard the description of new hallucinogens as a threat.

Colliding Beams

from a High Energy Physics Correspondent

An experiment which yields in all qualitative respects the theoretically predicted results and which has intrinsic novelty and elegance as well was reported at the recent High Energy Physics Conference in Heidelberg. H. Joos of the DESY group in West Germany reported the results of an experiment performed by a Russian group at Novosibirsk which has studied the annihilation of an electron and a positron and the subsequent production of a pair of π mesons with opposite This experiment, like similar experiments being performed at Orsay in France and Stanford in the United States, relies on the very recent experimental technique of making two beams of particles collide. The advantage of this method lies in the relativistic kinematics of the situation in which the square of the beam energy in the colliding beam is a true measure of the usable energy. In the more conventional situations, with a beam striking a stationary target, usable energy is proportional to the product of beam energy and the mass of the target particle.

In principle, it is quite simple to perform a colliding beam experiment such as that carried out at DESY. The first step is to build a storage ring, which consists of the field magnets and vacuum system for a small synchrotron. This device can then be fed with electrons from some conventional synchrotron or linear accelerator until a considerable current accumulates. A similar beam of positrons is then built up, either as a separate beam in the same storage ring (but travelling in the opposite direction because of the charge) or in another storage ring so arranged as to form a figure of eight with the first. The two beams can then be made to collide and conventional detection methods used to observe the reaction products. Although the relative probability of a collision between the beams is low compared with that when a solid or liquid target is used, this disadvantage is somewhat offset by the several chances of collision afforded by the repeated intersections of the orbiting particles. In practice, the difficulties, arising chiefly from resonance effects which cause beam instabilities, are enormous and have taken several years to understand, so that the new experimentthe first in which a strongly interacting final state has been studied—represents a landmark in the field and is a tribute to the skill of the experimentalists involved.

Several years ago, studies of nuclear form factors obtained from measurements on the scattering of electrons by nucleons suggested the existence of a neutral particle with unit spin and a mass of several hundred MeV. This was later confirmed by the discovery of the p meson at a mass of some 760 MeV in pion production experiments. By invoking what is believed to be one of the basic principles of physics known as crossing symmetry, it is possible to infer that if this p meson couples electromagnetically to the electrons, which would account for the form factors, then an electron-positron pair should annihilate electromagnetically to form such a ρ meson which would then decay, by strong interaction, into a pair of charged pions. The new experiment confirms this concept in a most striking manner. When the number of pion pairs is plotted against energy, an almost classic Breit-Wigner resonance decay curve is seen with a peak at a mass value of 764 MeV and a width of 93 ± 15 MeV.

Although the immediate interest lies in the novelty of the experimental technique, detailed experiments along these lines seem certain to suggest a major revision of current ideas.

Reliable Electricity

from a Correspondent

Can the economic consequences of unreliability of electricity supply be properly quantified? From whose viewpoint should this task be attempted? What is the place of statistical and probability methods in such studies? How can the experience of various countries in this field be collated and compared? These and many other related questions were discussed at a conference last week organized by the Power Division of the Institution of Electrical Engineers. About 250 delegates, including 40 from 14 overseas countries, participated in three full-day sessions devoted to the problems of generation, transmission and distribution connected with this issue. It must be said at once that the questions remained largely unanswered, although many preliminary suggestions were advanced.

It is rare, if not unprecedented, for the product of the electricity supply industry to be examined in this way. In both national and international forums, the manufacturers of electrical plant are accustomed to describe the design and performance of their products and to face questions and criticism from customers and competitors. Publications by electricity supply engineers are commonly restricted to planning and operational problems. The papers at this conference clearly showed the reluctance felt by some authors to unveil the basis for the cost-benefit calculations which they may have attempted. Unfortunately their major customers, the large electricity using industries, played only a small part in the conference and, despite some shrewd blows, were heavily outnumbered by the supply side. The plant manufacturers appeared uncertain as to their proper role in these unusual proceedings and remained rather quiet.

The conference might therefore have been a rather tame affair, but it was saved by the excellent, frank and good-humoured contributions from abroad. A Danish engineer drew some interesting contrasts between electronic and nuclear equipment design and that of power plant and systems. Might it perhaps be both cheaper and more reliable to employ a certain amount of duplication and redundancy while lowering the performance specification for individual items?

The same speaker added, quixotically, that he felt a power cut now and then might serve to remind us of our ever increasing dependence upon the machinery of civilization and progress. He was not supported in this by a Swedish colleague, who was sure that their job was to build the biggest possible market for electricity by offering consumers what they want to buy. (This speaker also made the possibly significant point that the Swedish State Power Board supplies only 40 per cent of the country's electricity. Comparisons with other undertakings thus remain possible and provide a valuable stimulus to efficiency.) An engineer from Electricité de France was the contributor who laid most stress upon the concept of "loss to the community" resulting from failures of supply, and who demonstrated how far l'esprit cartésien penetrates into technico-economic assessments of national issues. Other valuable papers and discussions came from Germany, Poland, Netherlands, the United States and Canada. The differences between countries having much hydro-electric power and those lacking it were brought out in several contributions.

The central problem is best illustrated by an extreme example. A short, or even momentary, interruption to a £10 million petro-chemical complex can occasion a loss to its owner of perhaps 1,000 times the sale price of the electricity not used during the incident. This results from the disturbance and need for restarting procedures on a process designed (and costed) to be continuously operating. A long outage in the small hours on a commercial or domestic supply might pass unnoticed.

Plastid Nucleic Acids Again

from our Correspondent in Cell Biology

Study of the nucleic acids of plastids is rapidly becoming one of the great band wagons of biology. Two weeks ago (Nature, 216, 14; 1967) in this column I wrote about some experiments done by Smillie and his collaborators indicating that the DNA of Euglena chloroplasts codes for chloroplast ribosomal RNA. Since then Fukuhara (Proc. US Nat. Acad. Sci., 58, 1065; 1967) and Suyama (Biochemistry, 6, 2839; 1967) have reported that, in all probability, the DNA of mitochondria in the yeast S. cerevisiae and Tetrahymena codes for the RNA of the mitochondrial ribosomes. Suyama also reports the unexpected result that very little of the 4-58 soluble RNA in Tetrahymena mitochondria hybridizes with the mitochondrial DNA and even more puzzling—that it does not hybridize with the nuclear DNA either. Earlier this year Barnett reported three mitochondrial specific species of tRNA in Neurospora, and Suyama and Eyer (Biochem. Biophys. Res. Comm., 28, 746; 1967) found mitochondrial specific leucyl tRNA in Tetrahymena, so it was confidently expected that mitochondrial DNA codes for these organelle specific tRNAs. Unless, however, Suyama is in error, this idea must now be questioned.

Recently Küntzel and Noll described the sedimentation properties and nucleotide composition of Neurospora mitochondrial ribosomes (Nature, 215, 1340; 1967). Now Luck, well known for elegant studies of Neurospora mitochondrial DNA, and collaborators report a virtually identical study (Proc. US Nat. Acad. Sci., 58, 1025; 1967). The two groups report analyses of the nucleotide composition of Neurospora mitochondrial and cytoplasmic ribosomes that agree to within 5 per cent and show the two classes are quite distinct; for example, the G+C contents of mitochondrial and cytoplasmic ribosomes are 38 per cent and 49 per cent according to Küntzel and Noll and 35 per cent and 50 per cent according to Luck et al. But Luck's values for the sedimentation coefficients of the ribosomes and ribosomal RNA are unusually high and very different from those given by Küntzel and Noll. For example, under their conditions, Luck et al. find E. coli ribosomes sediment at 81.9S and Neurospora cytoplasmic and mitochondrial ribosomes have virtually identical (and high) coefficients, 89.8S and 89.5S, whereas Küntzel and Noll's corresponding values are 70S (the conventional value for E. coli) and 77S and 73S for the

two classes of *Neurospora* ribosomes which are thus clearly distinguishable. Since the two groups find similar nucleotide compositions for *Neurospora* ribosomes, these perplexing differences must be attributed to differences in conditions of sedimentation, notably in the composition of the buffer solutions.

Also in the current Proc. US Nat. Acad. Sci. (58, 1051; 1967), Attardi and Attardi report the very interesting discovery that in HeLa cells that fraction of the cytoplasmic mRNA associated with ribosomes bound to the endoplasmic reticulum is of cytoplasmic origin. When cells are fractionated after a 30 min pulse of H³ uridine, about twice as much of the newly synthesized RNA is associated with a membrane fraction, which contains mitochondria, endoplasmic reticulum and 10-15 per cent of the cell ribosomes as with free poly-This membrane associated RNA differs in base composition from the mRNA associated with free polysomes; it has a higher adenine and lower G+Ccontent. Furthermore, the membrane associated RNA has a faster turnover than free polysome mRNA, sedimentation properties characteristic of mRNA and greater sequence homology to cytoplasmic, presumably mitochondrial, DNA than nuclear DNA. Bacterial mRNA is much less stable than eucell mRNA and mitochondria are thought to have arisen from symbiotic bacteria. It seems significant to this idea that the mRNA in HeLa cells which is thought to originate in mitochondria is metabolically unstable. Attardi and Attardi suggest that some of the mRNA transcribed off mitochondrial DNA migrates into the cytoplasm where it associates with ribosomes bound to the endoplasmic reticulum and is translated. It will be of great interest to see what proteins it specifies.

Recording Active Brains

from a Neurophysiology Correspondent

ONE of the outstanding problems in neurophysiology is the development of techniques for recording neural activity in alert, active animals so as to permit proper correlation of neurophysiology and behaviour. At present most knowledge of the neurophysiology of the central nervous system is derived from anaesthetized preparations in which it is most unlikely that cerebral processes are similar to those in alert animals. The problems to be solved include the rigid mounting of a microelectrode the tip position of which can be finely controlled, and the precise stimulation of, say, the retina of an unrestrained animal.

Recently MacLean (Electroenceph. Clin. Neurophysiol., 22, 180; 1967) described a platform which can be mounted firmly on the cranium of an experimental animal, so that it lies in the horizontal plane of the stereo-taxic co-ordinate system. Guide holes within the platform allow the insertion of micro- and macroelectrodes through holes drilled in the cranium. However, although it is possible to implant permanent recording and stimulating macro-electrodes, the use of micro-electrodes is more difficult. They are introduced at the start of a recording session during which the animal must be restrained, for head movements may cause movement of the brain relative to the electrode. The technique is therefore limited; nevertheless, intra-cellular recordings have now been made from units in the squirrel monkey's hippocampus

(Yokota, Reeves and MacLean, Science, 157, 1072; 1967). The hippocampal cortex with a much simpler and more ordered structure than the rest of the cerebral cortex is suitable for investigating single unit activity, particularly the relation of unit firing to specific inputs producing known patterns of synaptic activation. The authors investigated the effects of two inputs, one from electrical stimulation of the olfactory bulbs and the other from the septum. The septal pathway produced EPSPs which could lead to spike initiation, whereas olfactory bulb stimulation never leads to spike generation.

Marg and Adams (Electroenceph. Clin. Neurophysiol., 23, 277; 1967) also describe techniques for electrode implantation but in human subjects. They have obtained recordings from units (producing spikes of low amplitude and long time-course) in the striate cortex, and say that these show some of the properties found by Hubel and Wiesel for the primary visual cortex of the cat; furthermore, this activity was inhibited when the subject closed his eyes. This is an interesting observation, as reduction of the intensity of light reaching the retina usually leads to increased activity in the optic nerve, presumably because lateral inhibition in the retina decreases, making the retina more sensitive but reducing visual acuity (Arduini, Progr. Brain Res., 1, 184; 1963).

Immunology of Reproduction

from a Correspondent

An International Symposium on the Immunology of Spermatozoa and Fertilization was held in Varna, Bulgaria, from September 27-29, 1967. Organized by Academician K. Bratnov and his colleagues, it attracted more than 340 delegates from 20 countries, most of them from the Soviet Union and eastern Western scientists there took this excellent opportunity to meet people and evaluate data previously unknown. All the proceedings, entertainment and accommodation were provided in the International House of Scientists, which gave excellent opportunities for informal discussion.

Progress on various topics was reported, although major questions inevitably remained unanswered. Several important antigens extracted from tissues or secretions of the male tract have been characterized. Some of them in seminal plasma adhere so tightly to spermatozoa that they influence the antigenic properties of these cells. Immune aspermatogenesis received much attention, ranging from the identification of some of the antigens responsible to the physiological consequences of natural or experimental interference with normal processes. But the mechanism by which the antibodies interfere with spermatogenesis is still not fully understood. Removal of the site of sperm resorption in men with blocked vas deferens leads to a reduction in their serum titre of spermagglutinins. But it is still not clear why some men transmit these antibodies to their seminal plasma whereas others do

The effect of immunization with spermatozoa on fertility in females was dealt with by eastern and western workers. In several species including man there is now evidence of impairment of fertility in females due partly to the presence of antibodies in the repro-

ductive trace.

Function of Histones

from a Corresponder.

THE relation of histones to the regulation is one of the most challenging and controvers. in developmental biology. Originally the Stedman. proposed that specific histones characterize specific cell types, but analyses of histones from different tissues do not support this idea. Genetic regulation must be at a more subtle level of histone chemistry. Allfrey and Mirsky and their colleagues have claimed that acetylation and phosphorylation of histones is a prerequisite for RNA synthesis at histone-repressed gene loci. Experiments by Gutierrez Hnilica (Science, 157, 1324; 1967) tend to support this idea. They have found that the differentiated cells of rat liver and spleen incorporate phosphate-32 into their lysine-rich and arginine-rich histones at a very much faster rate than the dividing cells of regenerating liver and transplanted Novikoff hepatoma, although the latter cells synthesize more histone than the differentiated cells. Furthermore, the degree of phosphorylation decreases with increasing rate of cell division. Thus it seems, on the basis of the degree of phosphorylation, that differentiated cells are more genetically active than the dividing cells.

It should be possible to detect changes in histone biochemistry at genetically active sites, like the "puffs" of Dipteran polytene chromosomes. This led Ellgard (Science, 157, 1070; 1967) to induce puffs on the polytene chromosomes of Drosophila larvae and to look for evidence of acetylation at the puffs. By autoradiography he found that the newly induced puffs were genetically active and they incorporated 3H-uridine into RNA, but he was unable to find any evidence of acetylation at these sites. So controversy remains.

Some pattern does seem to be emerging in the relation of histone type with division and differentiation. Holoubek and Hnilica (J. Nat. Cancer Inst., 39, 187; 1967) report that a histone very rich in lysine (F1) extracted from nuclei of the Walker carcinosarcoma of mouse, and normal thymus and liver cells, when injected into mice increases the rate of DNA synthesis in the nuclei of their liver and spleen. Other histones, including the arginine-rich fractions (F2a and F3), inhibit synthesis. It is interesting that the F1 fractions from thymus and liver nuclei have to be separated from some unspecified protein before being able to stimulate this protein. Other this protein. Other this protein. Other this protein. Other this protein of a lysine-atheris, is provided by Acta, 145, 531; 1967). Se ascites cells reduces DNA and cells end while synthesis of RNA and the synthesis about 35 per cent, but the very thore historis reduced by 60 per cent. So nich procee is an intimate association between the third in the synthesis of the very lysine-

ine-rich histones are considered to be ac of stable, non-dividing cells by Evans rs (Exp. Mol. Pathol., 7, 105; 1967). They some of the histones from the tumour induced Shope papilloma virus. The tumour contains ginase, and the histones, not surprisingly, contain educed arginine level. This has the effect of raising he relative level of lysine in the histone, and it is tempting to think that this leads to the onset of unregulated division and tumour initiation. Can the transition from division to differentiation really be mediated by the lysine-arginine balance?

Recognition and Conformation

from our Molecular Biology Correspondent

Some striking examples have been described which uphold the dogma of protein chemistry that the aminoacid sequence of a chain uniquely determines its conformation, and show in addition that the association of different chains may be required if the information contained in their sequence is to be expressed. The first example follows on one of the recent achievements of synthetic peptide chemistry, the total synthesis of insulin, reported simultaneously by Katsoyannis and his co-workers and by a group working in China. Although it has long been established that correct internal disulphide pairings are preferentially formed in relation to incorrect ones when a single chain is allowed to refold from the reduced unfolded state, insulin, which has two chains joined by two of its three disulphide bonds, for a long time eluded attempts at correct recombination. Until the successful syntheses reported last year it was indeed often surmised that proper refolding and correct disulphide pairing could not occur independently of biosynthesis of the chains. This is now known not to be the case, and further details of recombination experiments have just been reported by Katsoyannis et al. (Biochemistry, 6, 2642; 1967).

If all three disulphide bonds of insulin are broken and allowed to reform, several intra-chain and interchain combinations will clearly be feasible. In practice, under defined conditions, recombination of A and B chains gives rise to only six products, which have been separated by ion-exchange chromatography. Two of these have the composition of A chains, two others that of B chains. It is not reported whether these contain inter- or intra-chain bonds, but it is in any event clear that only a small number of the possible pairings are sterically favoured. The remaining two components are both hormonally active and one is indistinguishable from native insulin. The nature of the other is unknown, and its proportion is determined

by the precise conditions of recombination. It can, however, be converted into its native isomer by precipitation with picric acid. Katsoyannis *et al.* (*ibid.*, 2656) have also prepared hybrid insulins from chains of different species, natural or synthetic, and fully active products have been obtained in yields ranging up to 50 per cent.

An important case of specificity of association between polypeptide chains occurs in antibodies. Immunoglobulins contain four chains, which are of two types, known as heavy (H) and light (L). Hybrid immunoglobulin molecules can be prepared, but it has been shown by Mannik that there is preferential recombination of H and L chains originating from the same The antibody activity of the molecular species. homologous species is also higher than that of the hybrids. Dorrington, Zarlengo and Tanford (Proc. US Nat. Acad. Sci., 58, 996; 1967) have now found physical evidence of a specific conformational interaction between homologous chains by the use of optical rotatory dispersion. The separated H and L chains each show a single Cotton effect maximum at 220-230 m μ , but the intact immunoglobulin—as previously noted by Steiner and Lowey-shows a pattern in which the rotation is smaller, and at least three component Cotton effects can be discerned. Dorrington et al. find that this curve is completely regained when H and L chains from myeloma immunoglobulin are recombined. It is striking that recombination of heterologous chains—as in the case of a normal heterogeneous non-specific immunoglobulin-generates only a part of the pristine pattern, a minimum at about $240~\mathrm{m}\mu$ being lost. Thus \tilde{H} and L chains will recognize each other and combine in specific manner, but a further interaction occurs only in the homologous case. It should be noted that the Cotton effects are very small, and not of a kind to suggest the presence or involvement of, for example, α-helical structure. The conformational change could be confined to a very few residues, or such an effect could arise from large perturbation of a few chromophores, for example, by juxtaposition with charged groups.

Yet another instance of a recognition process between two chains leading to specific refolding is described by Taniuchi, Anfinsen and Sodja (*ibid.*, 1235), who find that a staphylococcal nuclease of 149 residues can be cleaved by trypsin in the presence of inhibitor and calcium ions into three fragments of 5, 44 and 100 residues. The two large fragments can then recombine non-covalently, when 8 per cent of the enzyme activity is regained. The system therefore recalls the subtilisin-modified ribonuclease of Richards, in which two fragments recombine to give substantially the activity of the native enzyme. The present case is particularly interesting because the structure is stabilized despite the absence of disulphide cross-links in this protein.

Chain Termination

from our Cell Biology Correspondent

Last year Adams and Capecchi discovered that the initiation of protein synthesis in *E. coli* requires the insertion of N-formylmethionine as the first aminoterminal amino-acid of the polypeptide chain. Since then, Capecchi has been working on the more intractable problem of how the synthesis of a polypeptide

chain is terminated and the completed chain released from the ribosome-mRNA complex to which it is bound by the tRNA molecule carrying the last amino-acid incorporated. There must be a mechanism for reading the chain terminating codon (three codons UAA, UAG, and UGA can code for chain termination) and cleaving the last peptidyl-tRNA bond. In Biochem. Biophys. Res. Comm., 28, 773 (1967) he describes an experimental system devised to give a rapid assay for chain termination, and in Proc. US Nat. Acad. Sci., 58, 1144 (1967) he reports the discovery of an enzyme required for termination.

The assay for termination employs the RNA from an amber mutant of the coat protein gene of the RNA bacteriophage R17. This mutant has an amber codon, UAG, at the position of the sixth amino-acid, a glutamine residue, in the R17 coat protein molecule. In a cell free system the mutant RNA directs the synthesis of a small N-terminal peptide of the coat protein with the sequence N-formylmet-ala-ser-aspn-phe-thr; the next amino-acid in the coat protein is glutamine, but with the mutant RNA the amber codon causes premature termination of synthesis and the release of the hexapeptide. The great virtue of this system is that the unterminated peptide still attached to the peptidyltRNA can be distinguished from the terminated peptide released from the tRNA and the amounts of each measured. Furthermore, starving the system for any one of the six amino-acids in the peptide arrests the translation machinery before it reaches the UAG codon so termination can be controlled.

Exploiting this procedure, Capecchi isolated a complex of ribosome, mRNA and pentapeptide

attached by the phenylalanyl tRNA simply by starving for threonine. With this he has been able to define the conditions necessary for termination; incubating the complex under suitable conditions with or without threonine or supernatant enzymes showed that to get release it is necessary but not sufficient to complete the peptide by incorporating threonine and that release is not solely dependent on the transfer enzymes required to move the ribosome from the threonyl codon to the UAG terminating codon. Release does, however, depend upon the presence of a supernatant factor. This factor, with a molecular weight of between 40,000 and 50,000, sediments between 3.5S and 4.5S. Because its releasing activity is not affected by RNase, it cannot be an RNA-protein complex. Apparently the substrate of the release enzyme is the ribosome-mRNA-peptidyl tRNA complex so that it must act directly at the ribosome and not cleave the tRNA from peptidyl-tRNA already released into the supernatant, which was the other possibility.

Capecchi does not yet know whether the release enzyme works alone or in conjunction with other factors, in particular a hypothetical chain termination tRNA which reads the termination codon but does not carry an amino-acid. Many people, including Capecchi, have searched in vain for such a tRNA species, and although negative results can never exclude the possibility that such tRNA exists it is reasonable to think about alternative models in which the terminating codons are read either by the ribosome or the release enzyme or in which nonsense codons function simply because they cannot be read at all. Further characterization of the release enzyme could well decide the issue.

Chlorinated Hydrocarbons in British Wildlife

by D. C. HOLMES J. H. SIMMONS J. O'G. TATTON

Laboratory of the Government Chemist, London

Polychlorobiphenyl compounds have been detected in British wildlife. In birds' livers and eggs they are often in greater quantities than organochlorine pesticide residues. Polychlorobiphenyls are known to be toxic, and their detection in wildlife raises the question of the adverse effect they may have.

When wild birds' eggs or the livers of British wildlife are examined by gas-liquid chromatography (GLC) using electron-capture detection, peaks corresponding to such organochlorine pesticides as BHC, dieldrin and DDT, and their metabolites and breakdown products, often appear on the resultant chromatograms. These peaks sometimes represent amounts which are significant from a toxicological point of view, but the sensitivity of modern instruments also enables completely insignificant amounts to be detected. Analysts concerned with the determination of organochlorine pesticides in wildlife, however, have long been aware that it is not unusual for an additional series of as many as ten peaks, corresponding to unidentified compounds, also to appear on these chromatograms¹⁻⁴. Little is known of the structure and origin of these compounds, but Roburn¹ established that they are organo-

chlorine in nature, with a substantial chlorine content.

and consequently possess electron-capturing properties.

On silicone or 'Apiezon' GLC columns, the series of peaks for these compounds normally begins at the point at which pp'-TDE and pp'-DDT are emerging from the columns and extends, in terms of retention times, to four or five times that of pp'-DDT, which is the last of the commonly occurring pesticides to emerge.

Before examination by GLC, samples have normally been subjected to a fairly rigorous clean-up procedure, such as that of de Faubert Maunder et al.⁵, which includes a dimethylformamide—hexane partition and passage through a column of prepared alumina. Because these unknown compounds are similar in nature and properties to the organochlorine pesticides, they also pass through this and similar clean-up procedures; consequently, they

often interfere seriously with determinations of pp'-TDE and pp'-DDT in wildlife because of overlapping of the chromatographic peaks. Suitable procedures have been devised to overcome this difficulty of interfering peaks. One method is to effect a better resolution of these particular peaks by choice of a suitable stationary phase for GLČ6. Another method, which also demonstrates the presence of these compounds in the sample, is the use of a preliminary thin-layer chromatographic treatment?. The cleaned-up extracts are examined on silica gel chromatoplates using a 1 per cent solution of acetone in hexane as mobile phase2. Spots corresponding to the compounds can then be found at R_F values between 0.8 and 1.0, whereas the commonly occurring organochlorine pesticides and their metabolites produce spots of lower R_F values. A similar separation can also be shown with reverse phase paper chromatography⁸ whereby the unknown compounds move only a very short distance from the base line compared with the pesticides and their metabolites.

Gas-liquid chromatography using dual channel detection systems with separate electron-capture and flame-ionization detectors has also been used to demonstrate the presence of large amounts of weakly electron-capturing material, in addition to known pesticide residues, in the eggs of oyster catchers (Haematopus ostralegus)⁹.

Experience in this laboratory has shown that these compounds occur most frequently and in the largest proportions in the livers, fat and eggs of birds, particularly terrestrial predators such as sparrowhawks (Accipiter nisus) and kestrels (Falco tinnunculus) and marine feeders such as guillemots (Uria aalge) and kittiwakes (Rissa tridactyla); they also commonly occur in freshwater fish. We have detected small amounts in human and animal fat samples, but less frequently and in much smaller proportions than in avian samples.

A similar series of chromatographic peaks has been observed by Holden^{10,11} when examining extracts of seals and fish taken in Scottish waters. He found that the peaks given by the extracts of fresh and sea-water fish represented fairly low concentrations, but those given by extracts of seal blubber corresponded to much larger proportions, of the order found by this laboratory in birds' eggs.

Despite considerable curiosity about the identity of these compounds, little progress has been made in identifying them, but there has long been a general supposition that they were either further breakdown or condensation products of the organochlorine pesticides or possibly loose compounds of these with natural products such as protein matter.

Jensen, however, succeeded in identifying a series of such peaks as corresponding to polychlorobiphenyl compounds, in 200 pike taken in different parts of Sweden, and in an eagle¹². We have now been able to show that the long retention time compounds occurring in British wildlife are also polychlorobiphenyl compounds.

Polychlorinated biphenyl has been in common commercial use for some time as a plasticizer in paints, resins and plastics. It also has electrical insulating properties and can be used for a number of other protective purposes. Commercial preparations of this material are usually graded according to the degree of chlorination, but all of them are substantially complex mixtures of polychlorobiphenyl compounds that could be expected to resemble the organochlorine pesticides in their chemical and physical

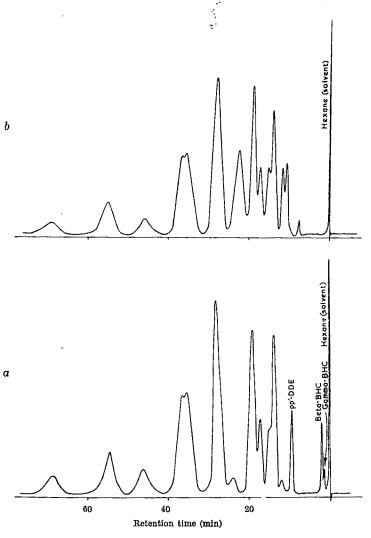

Fig. 1. Gas-liquid chromatogram of (a) extract of kestrel liver and (b) a commercial polychlorobiphenyl resin.

properties. In the prescribed extraction and GLC conditions, these mixtures produce a series of chromatographic peaks of the type in question.

The compounds occurring in British wildlife correspond to the more highly chlorinated biphenyl compounds rather than the more lightly chlorinated types. These highly chlorinated biphenyls also occur to some extent in the analogous polychloroterphenyl preparations which have commercial uses similar to those of polychlorobiphenyl. It is possible that some of the compounds with very long retention times occurring in British wildlife are lightly chlorinated polychloroterphenyl compounds.

Fig. 1a shows the gas-liquid chromatogram of an extract from a kestrel liver. The peaks corresponding to pp'-DDE (0.43 ng), beta-BHC (0.33 ng) and gamma-BHC (0.03 ng) are labelled. The other peaks form the series referred to above and until now would have been regarded simply as "unknown organochlorine compounds not corresponding to any known pesticide or its metabolites". Fig. 1b shows the analogous chromatogram of a commercial polychlorobiphenyl resin. So far as retention times are concerned and apart from the pesticide peaks, there is exact matching for all but a few peaks in the two chromatograms.

The chromatograms shown were obtained by use of a silicone gum (GE-SE 52) column, but this precise correspondence between the retention times of the peaks for the unknown compounds and those from the polychlorobiphenyl resin has also been demonstrated on 'Apiezon L'

and cyanosilicone columns. The actual retention times recorded for the peaks on these three types of column are given in Table 1.

Further confirmation as to the identity of these compounds has been obtained by a study of their behaviour on thin-layer chromatoplates, alumina and silica gel absorption columns and reverse phase paper chromatograms. In addition, these compounds have been shown to resemble the polychlorobiphenyl compounds in their chemical inertness. Thus they are not easily modified by simple chemical reactions to produce readily identifiable shifts in their retention times on GLC as can be done, for instance, to pp'-DDT by hydrolysing it to pp'-DDE or to aldrin by oxidizing it to dieldrin.

A number of livers and eggs taken from birds in the British Isles or their coastal waters have been examined in this laboratory with results similar to those obtained for the kestrel liver referred to earlier. While the identification of these compounds in British wildlife may solve the mystery of these peaks on GLC chromatograms, it raises, however, many other questions. Why, for example, do these compounds seem to be accumulated, most frequently and in the largest proportions, in certain types of wildlife such as birds, seals and fish, and only at the most in very small proportions in man or his domestic animals such as cows or sheep? In this respect they seem to differ markedly from the organochlorine pesticides which seem to have invaded nearly all aspects of our environment and to which they bear a strong resemblance chemically and physically.

Some of the samples of birds examined in this laboratory have seemed to contain higher proportions of polychlorobiphenyl compounds than organochlorine pesticides. For example, the peaks on the chromatogram for the kestrel liver shown in Fig. 1 were estimated to be equivalent to about 12 ng of polychlorobiphenyl compounds. must be contrasted against the organochlorine pesticide residues listed above. These total only about 0.8 ng of which 0.33 ng is beta-BHC, an isomer of BHC which is generally regarded as non-toxic to wildlife.

Great concern has often been expressed by conservationists about the effects of pesticides on wildlife, particularly birds. The identification of these other organochlorine compounds in wildlife prompts enquiries as to the possible toxic effects they may be having. That these compounds are toxic is generally agreed^{13,14}; the polychlorobiphenyls are in fact regarded as an industrial hazard and threshold limits for them in air have been advised16.

We thank the Nature Conservancy for samples of wildlife and Monsanto Chemicals Ltd. for samples of polychlorobiphenyl resins.

Quasi-stellar Sources, Supernovae and Novae

P. F. BROWNE University of Manchester Institute of Science and Technology

By considering the opacity of a surface layer of a star, the author concludes that quasi-stellar sources, supernovae and novae may be different manifestations of the same mechanism.

Ir is usually considered that the outbursts of novae and supernovae are fundamentally different processes, but I shall here propose a mechanism which can account for both phenomena, and which at the same time can account for other problems concerned with quasi-stellar sources (quasars). In particular, I suggest that these outbursts are likely to be anisotropic (as indeed they are observed to be for novae). Because the energy released during a supernova outburst is comparable with the stellar rest energy, an anisotropic outburst could mean that the star is accelerated to relativistic velocity in order to conserve momentum, thus affording a Doppler explanation of the large red-shifts of the quasi-stellar sources.

Consider the opacity of a layer, L, at the surface of a star. Let ΔR be the thickness and R the radius of L, and let L contain plasma at temperature, T, with electron and positive ion densities N_t and N_t respectively. L will be opaque to radiation of wavelength λ provided that τ is about I, where τ is the optical depth of L. A major contribution to τ is τ_{ff} , the optical thickness due to free-free absorptions. It is known that $\tau_{ff} \propto \lambda^2 T^{-3/2} N_e N_f \Delta R$ (ref. 1). where induced emissions are included. Suppose, now, that L is compressed or dilated without changing the total numbers of ions; that is, ΔR is varied under conditions which maintain constant $4\pi R^2 \Delta R N_e$, so that $\Delta R N_e =$ constant. Evidently $\tau_{ff} \propto N_e N_i \Delta R \propto N_i \propto 1/\Delta R$. Thus compression of L increases its opacity, while dilation reduces the opacity.

Of course, the total number of ions will not remain constant in practice, because the recombination rate is proportional to N_eN_i . If the percentage of atoms ionized is large, the density of unionized atoms, N, will therefore be proportional to N_cN_i . This means that the contribution to the opacity made by bound-bound and bound-free transitions within unionized atoms is also proportional to $N_e N_i \Delta R$. This effect, recognized to be important for stellar pulsation^{2,3}, further increases the opacity of L on compression.

Some consequences of this variable surface opacity will now be examined. Under equilibrium conditions the luminosity of the star, S, must equal the power, P, which is generated by thermonuclear processes in the interior. The temperature of L will then be such that it radiates as much power as it absorbs. At this temperature and thickness, L has its equilibrium opacity. If, now, L is compressed, the decrease of ΔR increases the opacity of L, thus partially stemming the flow of radiation from the interior. As a result, S decreases below P, leading to an increase with time of the radiation density (and hence the temperature) inside the star. How is this situation relieved?

Ultimately L could regain its equilibrium opacity by absorbing heat from the interior (adiabatic heating during compression is quite insufficient). For radiation of wavelength λ , the rise in temperature of L would have to be such that $T^{-3} {}^{12} \Delta R = \text{constant}$; the temperature increase must be even greater if we consider a change of equilibrium opacity to the total radiation (all λ) which is proportional to $T^{-3.5}$ (ref. 4). Before, however, the opacity can return to equilibrium by this mechanism, which will be comparatively slow, the build-up of radiant energy within the star is likely to cause other changes.

The rise in temperature in the interior of the star, following the partial damming of the radiation flux by L, will in most cases cause thermal expansion of the whole star. L will be thrown outward, probably rather violently. Before it can fall back under gravity ΔR will increase, thus reducing the opacity of L and allowing the trapped radiation to escape. The interior now cools, so that the star contracts, and L returns to its original state of greater than equilibrium opacity. The cycle then recommences. L behaves as a valve for the control of the outflow of radiation, alternately opening a little and closing a little. Thus a pulsation is initiated and maintained by thermal energy. This process is well recognized^{2,3}; what is new is the important contribution made by free-free absorptions to the variable opacity of the surface layer.

A thermally driven pulsation, by its very nature, is likely to be rather irregular. The erratic light variations of the irregular variables can be thus explained. In order to account for the exceedingly regular variations of the cepheids and long period variables the thermal pulsation must be synchronized to a natural acoustical mode of the star; the occurrence of resonance between the thermal pulsation and a natural mode would both regularize and amplify the pulsation. The success of Eddington's calculations of the periods of pulsation is then understandable. The resonance condition could also account for the very sharp onset and cessation of pulsation in the H-R diagram.

The following observations lend strong support to the theory. (a) Maximum luminosity would be expected at the phase when L becomes transparent, which will be about one quarter of a period after maximum contraction and about the time when the outward velocity is a maximum. This is observed in cepheids. (b) As $\tau_{ff} \propto \lambda^2$, L will become transparent to short \(\lambda \) before long \(\lambda \). Thus, a progressive retardation of phase of the light curve with increasing λ is expected. This is observed in both cepheids and long period variables. (c) The amplitude of the light curve should be very much greater for wavelengths such that τ is about I than for longer or shorter wavelengths. Longer wavelength radiation will originate within L itself, and will not therefore be subject to valve Shorter wavelength radiation will not be appreciably absorbed by L and will not therefore be affected by any change in L's opacity. This effect is particularly marked in the long period variables.

(d) Particularly convincing are suppression phenomena observed in certain stars whose surface layer, L, happens to be subject to sporadic changes. The 387 day oscillation of luminosity in R Aquarii is sometimes suppressed for several years, during which time the star appears bluer and shows all the spectroscopic evidence of high temperature. Payne-Gaposchkin' mentions that an inner layer is probably exposed at such times as a result of dispersal of

surface absorbing material. The fact that the 387 day oscillation disappears with the dispersal of this materia indicates that the surface absorption is primarily respon sible for the oscillation. VV Pup, an RR Lyrae variable with a 100 minute oscillation, shows similar behaviour. In this case, however, the surface layer is not dispersed but thickened, or at least rendered too opaque to act as an effective valve, because the disappearance of the oscillation coincided with dimming of the star by 3 magnitudes; the oscillation eventually reappeared with continuity of phases. In RU Cam, a cepheid with an unusual phase relationship between the light and radial velocity curves, the variability has apparently disappeared altogethers.

Suppose, now, that the star is partially degenerate. Within a degenerate star (which is density ionized) the pressure is exerted by that relatively small fraction of the electrons which occupy states near the top of the Fermi distribution. As pressure is proportional to N_ckT , the smallness of N_c and the largeness of the pressure imply an exceedingly large T. In the core of such a star pressure is exerted by a low density of extremely high temperature electrons. Because most electrons cannot make transitions to unoccupied states and because the probability of transitions is very small for the small percentage that can (due to large T), a degenerate core has very low opacity and high thermal conductivity. The star consists of an isothermal core at high temperature overlaid by a thin stratum of non-degenerate gas which supports the entire temperature gradient.

Should the surface layer of such a star develop an opacity greater than the equilibrium opacity, the radiation density within the star will build up without an associated increase of temperature. The unstable situation cannot now be relieved by thermal expansion as in the case of the pulsators. I suggest that the internal radiation density increases gradually until radiation pressure is sufficient to blow away the opaque skin layer, L. This will bring about a sudden and very large increase of luminosity, which is sufficient to account for novae and supernovae. The increase in luminosity for ordinary novae is a factor of 105, and for type I supernovae 108. The broad spectrum of nova phenomena (the energies liberated vary from 10³⁸⁻⁵ erg for dwarf novae, through 1045 erg for ordinary novae, to 1048 erg and 1051 erg for types II and I supernovae) can have a common explanation in terms of a sharp reduction of surface opacity.

Spectroscopic evidence indicates that about 1028 g of material is expelled in a nova outburst. In order that radiation pressure should be able to lift off this mass against gravity (for a star of mass $1 M_{\odot}$ and radius $0.1 R_{\odot}$), the effective internal temperature must rise to 7×10^8 ° K. This will be the temperature of the exposed sub-layer immediately after the removal of L. If the initial effective temperature was 50,000° K, then it is a simple consequence of Stefan's law that the bolometric magnitude increases by $\Delta m_{bol} = -25$. This is probably very reasonable in relation to the observed increase in the photographic magnitude, namely $\Delta m_{pg} = -12.5$. Standard bolometric corrections cannot be applied, because at X-ray wavelengths the layer, L, is probably optically thin, a conclusion supported by the recent observation of X-rays from such a star¹⁰. In the case of a supernova it might be assumed that $\Delta m_{bol} = -30$ as $\Delta m_{pg} = -19$ is observed. This would imply that the effective temperature at the inner surface of L is 10^3 times that at the outer surface. The corresponding radiation pressure would be sufficient to lift off 1.5×10^{31} g.

The spectroscopic properties of novae are now easily understood: (i) Kopal¹¹ finds it difficult to understand why the largest violet shifts should be recorded for absorption lines rather than emission lines. As the temperature of the effective photosphere falls by a factor of only five or six while the radius expands by a factor of 1,000, Kopal argues that the emission must come from a shock front which preserves a high density. It is this conclusion that

introduces the absorption line problem. The present theory indicates that the broad emission comes from the underlying star, and that the most rapidly expanding material, at least initially, is the absorbing shell L.

(ii) Following the departure of L, there will be a strong stellar wind because of the large temperature gradient. Initially, this wind will be a fully ionized plasma which emits only a continuum. On cooling sufficiently for recombinations to occur, a spectacular change to a line spectrum is expected. This is observed in the emergence of the principal spectrum.

of the principal spectrum.

(iii) The impact of the stellar wind on the more slowly expanding shell, L, causes further spectroscopic changes. The diffuse enhanced spectrum of short duration bears evidence of the impact. A shock front caused by the impact may be reflected back and forth between L and the star, accounting for periodic dips in the light curve and

for oscillatory emission line shapes12.

The time scale for rise to maximum will be the time scale for L to become transparent. For novae the rise time is about a day, and because the expansion velocity of L (as estimated from the premaximum absorption spectrum) is of order 1,000 km/sec the shell evidently expands to $100\,R_\odot$ (a factor of 1,000) before becoming wholly transparent. Such a large expansion indicates that it is expelled as a shock front. The time scale for decline will be the time scale for the formation of a new surface layer, L, of high opacity, and will therefore depend on the rate of cooling. Decline times are observed to vary greatly; fast novae decline by 3 magnitudes in about 30 days, slow novae in about 200 days.

If the opacity of the newly formed surface layer is greater than the equilibrium opacity, the radiation density will again build up within the star, and the outburst will recur. Thus, the recurrence of novae is

easily explained.

The opaque skin layer, L, is unlikely to be of uniform thickness and density. Rotation, or surface magnetic fields, would disturb the spherical symmetry. Radiation pressure is therefore more likely to puncture the shell (as a bursting balloon) than to expand it uniformly; a window may be blown out of L at one or more localized regions. The patchy nature of the nebulosity surrounding old novae, and the knots which appear in the Doppler ellipses in spectrograms taken with the slit across the source¹², leave no doubt that many nova outbursts are anisotropic. This anisotropy is of the greatest significance in the following theory of quasi-stellar sources.

If some fraction of the radiant energy emitted during the outburst of a nova or supernova is anisotropic, then in order to balance the resultant momentum of the radiation, the star must acquire a recoil velocity. If $F(\theta, \varphi)$ is the flux through the surface in a direction defined (relative to the direction of resultant momentum) by the polar angles, θ and φ , then an anisotropic luminosity, S, can be defined by $S = R^2 \iint F(\theta, \varphi) \cos\theta \sin\theta d\theta d\varphi$. The energy liberated anisotropically is $E = \int S dt$. The resultant momentum of the radiation is E/o, and the recoil velocity of the star (mass M) is v = E/Mc. This velocity will be relativistic if $E \sim Mc^2$. For $M = 1M_{\odot}$, this implies $E \sim 1.8 \times 10^{54}$ erg. According to Zwicky13 the surface temperature at the initial stages of a supernova may reach 3 × 106 °K, and the total radiant energy liberated will lie in the range 1051-1055 erg. Thus, even neglecting the momentum carried off by expelled matter, it is possible for such stars to be accelerated to relativistic velocity.

A star which has been accelerated to a relativistic velocity will soon escape from the Galaxy. If the frequency of occurrence of supernovae is of order 1 per galaxy per 400 yr, and if the quasi-stellar sources are old supernovae now receding from the Galaxy with relativistic velocity, then in order to obtain say 10^5 quasi-stellar sources we must go back in time 4×10^7 yr and therefore out in distance 3–10 Mparsec. Another limitation on distance is imposed by the absence of detectable proper motions¹⁴.

If x is the perpendicular distance from the Earth to the trajectory of a quasi-stellar source whose distance is now d and velocity v, then the component of velocity transverse to the line of sight is xv/d, which corresponds to an angular motion of $\theta = 6.5 \times 10^{12} vx/d^2$ sec of are/yr. If x > 1 kparsec and $\theta < 0.0025$ sec of are/yr, one deduces d > 100 kparsec for v = 0.37 c.

The present flux from 3C 273 in the visible range is 1.3×10^{-10} erg sec⁻¹ cm⁻² (ref. 15). At a distance of 100 kparsec this implies a luminosity of 1.5×10^{38} erg/sec which is of the order of the luminosity of novae during outburst. Actually, 3C 273 is perhaps slightly exceptional; at the same distance most quasi-stellar sources would have only about one hundredth of 3C 273's luminosity of 3C 2

inosity.

The persistence of high luminosity suggests that there may be a new type of nova outburst—a stabilized nova. Suppose, for example, that the opaque skin layer, L, were punctured by a tube of magnetic flux, creating what is essentially a window to the hot interior. circumstances the cooling of the interior might become sufficiently slow to be balanced by the internal radiation build-up; by concentrating all its luminosity through the window in L the star may be able to keep this window open—any tendency for L to reform at the leak would be opposed by a strong stellar wind. The existence of objects like y Carinae, which remained at maximum for 20 years, gives plausibility to the suggestion. Assuming a constant luminosity confined to solid angle, $\delta\Omega$, the constant acceleration of the star will be S/Mc. Its red-shift after time t will be $z = St/Mc^2$, and when its red-shift is z its distance will be $d=z^2Mc^3/2S$. The total flux at Earth will be $f=z^2Mc^3/2d^3\delta\Omega$. Knowing f, z, and $\delta\Omega$, d can be deduced. For 3C 273 substitute $f = 1.3 \times 10^{-10}$ erg sec⁻¹ cm⁻² (neglecting flux outside the visible), z=0.158, and $\delta\Omega = 0.1$ (an assumption), which gives d = 1.2 Mparsec.

The stabilized nova hypothesis has other attractive consequences. (i) The red-shift builds up gradually and becomes large only at large distances. This introduces a correlation between red-shift and apparent magnitude, for which there is evidence 16.17. (ii) As the sources continue to radiate anisotropically, they will be visible only when viewed from the galaxy from which they have originated; thus large blue-shifts for quasi-stellar sources which have been emitted from a nearby galaxy have not been observed simply because they are not visible to us.

In two respects this theory is very successful. The first success is a natural explanation for the smaller red-shifts of absorption lines relative to emission lines in many sources¹⁸. The differences of red-shifts imply that absorbing material is escaping from the sources with velocities usually found only in novae or supernovae, for example 1,000 km/sec for 3C 191, 3,300 km/sec for PKS 0119-04, 17,000 km/sec for PKS 1116+12, 25,900 km/sec (and also 1,950 km/sec) for PKS 0237-23, and 33,000 km/sec for Ton 1,530. The expulsion of the material may be the result of minor outbursts; these have been witnessed (within the small time scale of our observations) in 3C 446¹⁹⁻²⁰, in 3C 345²⁷, and in 3C 273²⁸ (during 1927-29). These outbursts show that activity is still present, thus favouring the stabilized nova over the supernova hypothesis.

The second major success is that the variability of the quasi-stellar sources is accounted for, and would in fact be expected. The variability is remarkably similar to that found in old novae^{29,30}, a fact noted relatively early by Matthews and Sandage³¹. All fluctuations could be attributed to variable surface opacity. The rapid small amplitude variations (flickering) might be due to convection in the opaque skin layer of a partially degenerate star, because, as has been shown, such a layer has a very large temperature gradient. The more drastic outbursts mentioned above may have the same explanation as the outbursts of a dwarf nova (see text). It seems significant that the peculiar colour of the quasi-stellar sources, so important for their identification, should be matched only by the

colour of SS Cyg and U Gem eruptive variables (dwarf novae)32. The frequent association of faint nebulosity with quasi-stellar sources31,33 is also understandable in the nova theory.

To conclude, I would draw attention to what seems to be a satisfactory derivation of the distance of 3C 273. Burbidge et al.³⁴ have given evidence for broadening of the emission lines in 3C 273 by electron scattering; the only competing theory would be an expanding nebula with a large velocity gradient (3,000 km/sec between inner and outer edges for a 50 Å line width). This Doppler explanation of line broadening cannot really be excluded in view of the likelihood of a strong stellar wind, and the evidence for large expansion velocities provided by the absorption lines in some sources. If, however, an optical depth to electron scattering of 0.8 is adopted, as suggested by Burbidge et al., then $N_e R_{neb} \simeq 10^{24}$ cm⁻², where R_{neb} is the radius of the nebula. It is very likely that the line emissions from 3C 273 arise in the nebula around the central source—in 3C 279 and in 3C 446 the line emissions do not fluctuate with the continuum23. From the presence of [OIII] Greenstein and Schmidt³⁵ infer $N_e \le 3 \times 10^7$ cm⁻³; from the presence of FeII but absence of [FeII] Wampler and Oke¹⁵ infer $N_e > 10^7$ cm⁻³ and probably $N_e \ge 10^8$ cm⁻³. If $N_e = 10^8$ cm⁻³ is adopted, then $R_{neb} = 10^{16}$ cm. temperature of the nebula is probably no greater than 10^4 $^{\circ}{\rm K}$, as otherwise the absence of CII $\lambda 1335$ when MgII λ2798 is present would be difficult to explain³⁴. With this temperature the upper level of the H β line has 0.1 times the equilibrium population³⁶. Then, in order to obtain the observed flux of H β emission, $3\cdot4\times10^{-12}$ erg sec⁻¹ cm⁻², one requires that $N_e^2R_{neb}^3/d^2=4\cdot5\times10^{14}$ cm⁻⁵. With the above values for N_e and R_{neb} it can be deduced that d=1.5 Mparsec. This is in remarkably close agreement with the distance derived from the stabilized nova hypothesis. Burbidge et al.34 give such an argument, but it does depend on the electron scattering explanation of line broadening. If, however, the optical depth to electron scattering is not as great as 0.8, then d < 1.5 Mparsec.

Acid Conversions of Hydrazoarenes

D. V. BANTHORPE ANTHONY COOPER C. K. INGOLD Department of Chemistry, University College, London

In a historical review combined with a consideration of their new work, the authors discuss rearrangement and disproportionation in the acid conversion of hydrazoarenes with particular reference to the one- and two-proton mechanisms.

THE acid-catalysed conversions of hydrazoarenes comprise the isomeric changes, collectively known as benzidine rearrangements, by which hydrazoarenes give variously named diaminobiaryls and aminodiarylamines, as shown Together with these isomerizations, reactions of disproportionation may occur: some of the hydrazo-compound becomes reduced to aniline bases (fission amines) and some oxidized to the azo-compound

The mechanism of the rearrangement has been debated for more than 60 years1. The primary difficulty has been to understand the drastic stereochemical convolutions that some of them involve. How does a hydrazobenzene turn itself inside out in its conversion to a benzidine without falling to pieces? The mechanism of disproportionation has been widely suspected to be dependent on that of rearrangement, and thus to present the second of two problems that have to be solved successively.

The first theories of the rearrangements, those of Tichwinsky and Stieglitz, both of 1903, assumed that the hydrazo-compound was split by the acid into independent fragments, which transferred their unsaturated bonds to other positions before they recombined. Tichwinsky assumed homolytic fission, and Stieglitz heterolytic fission. After 1911, when Wieland demonstrated extensive homolysis without benzidine rearrangement in tetra-arvlhydrazines, the theory of homolytic dissociation fell into disfavour. Before and in 1922, Jacobson showed, as others have since done more quantitatively, that ABtype hydrazobenzenes give only AB-type, and not AA-or BB-type, benzidines. Such demonstrations exclude homolytic dissociation, but they do not exclude heterolytic dissociations, because an unsymmetrical hydrazobenzene could break into parts whose charge distinctions would ensure that the same parts recombined. In 1933, however, Kidd and one of us observed, as Wheland and his co-workers have done since with greater precision, that mixed symmetrical hydrazobenzenes give only symmetrical rearrangement products. non-crossing in that form excludes all mechanisms based on dissociation, and from about that date it has been generally accepted that benzidine rearrangements are basically intramolecular. Thus after 30 years the escape route of dissociation from the original stereochemical difficulty became firmly closed.

Of the several theoretical approaches since tried, the most successful is that of the polar transition state. This idea was introduced by Hughes and one of us in 1941, and has been developed since, notably by the incorporation of a suggestion by Hammick and Mason in 1946. The only intermediate compounds which this theory assumes have ordinary benzenoid or quinonoid bonding: they are like the factor or the products, but with extra protons. But between such intermediates the theory provides transition states having at least two bonds of strongly polar character. This strong electrostatic bond content will confer on the bonds greater lengths and very much lower bending force constants than those possessed by ordinary bonds, characteristics which can be shown to permit energetically cheap shape changes drastic enough to meet the stereochemical requirements. The electrostatic bond character will shift as the system passes over its transition state, old bonds being finally broken in electrostatic form, and new bonds introduced electro-statically, to pass into covalencies as they shorten and stiffen.

Concerning the role of catalytic protons, van Loon showed in 1904, as Hammond and Shine did more precisely in 1950, that the rate of rearrangement of hydrazobenzene in an aqueous organic solvent is quadratic in hydrogen ions, that is, the rearrangement involves two catalytic protons. The same result was subsequently obtained by others for the conversions of a number of substituted hydrazobenzenes. This work of generalization threw up one anomalous result, obtained by Carlin and Odioso in 1954, namely an apparent order in acid of 1-6, instead of 2, in the rearrangement of o-hydrazotoluene.

Between 1962 and 1964 results were recorded²⁻⁴ which established the existence of independent, but occasionally concurrent, two-proton and one-proton mechanisms; isolated the one-proton mechanism in several examples; and established the intermediates of the early and late stages of both these mechanisms. It was shown that the additions of all catalytic protons, even the second when two are involved, are in pre-equilibria, that is, they are low-energy processes occurring near the beginning of the reaction path. It was also shown that those losses of aromatic protons which admit the formation of new bonds

are irreversible low-energy processes belonging to the end of the reaction path. The events of the central high-energy region of the reaction path, the region of transition states, could then be hypothetically but consistently described by the polar transition state theory. The same work brought the slow uncatalysed rearrangements of hydrazoarenes in polar solvents into the same family of rearrangement mechanisms.

The next steps were to establish more firmly the nature of the high-energy events in the acid-catalysed mechanisms and to define more closely the range of conversions, whether of isomerization or disproportionation, to which the descriptions given of them apply. These objects have now been advanced by the study of kinetics and products in correlation for the acid conversions of a selection of hydrazobenzenes, having substituents of known polar and steric quality.

Kinetic Forms of the Acid Conversions

The approach, in 1962, started by asking why the kinetic anomaly of o-hydrazotoluene had remained unique and why persistent attempts over 8 years to find a second example of an order in acid of less than 2 had failed. The tentative answer was that the polar transition state theory had not guided these attempts, though it tells one where to look for other low orders in acid, namely among hydrazobenzenes with substituents which supply electrons to their phenylimine rings and weaken an aniline base (by impairing charge solvation). Either factor promotes polarization of the protonated NN'-bond, and, if strong enough, could act sufficiently to do so without help from the other; but the two factors collaborate in the o-methyl substituent, and hence any other substituent in which both effects are stronger could be predicted to reduce kinetic order more effectively. The following two series of orders of effectiveness of aryl groups in hydrazoarenes were thus predicted:

α -naphthyl > β -naphthyl > o-tolyl > phenyl o-anisyl > o-tolyl > phenyl

The first of these series was experimentally verified in 1962. Two α -naphthyl groups gave pure, and two β -naphthyl nearly pure, one-proton kinetics; and two α -tolyl groups gave transitional kinetics of the quantitatively correct form^{2,4} for concurrent mechanisms.

Table 1. Kinetic orders in hydrogen ion for conversions of hydrazobenzenes by perchloric acid in 60 per cent aqueous dioxan

Substituents in Ph groups	Range of [H+] studled	Order* in H+	Notes
2-MeO, 2'-Me()	0.0001-0.05	1

4-Ph,	0.0040.6	2	
4-NO ₂ ,	2.0-4.0	2	

^{*} When using ranges of acidity rising to above 0.3 N, we replace [H+] by h_0 in the reckoning of kinetic orders.

a, Experiments by J. Roy. The apparent kinetic order rose with acidity, in accordance with the rate equation for concurrent independent mechanisms.

b. Experiments by M. O'Sullivan.

c. Variation of order as in note a.

d, Hydrochloric acld was substituted for perchloric acid.

Verification of the second series is contained in the subsequent results summarized in Table 1. One o-anisyl group acts like two o-tolyl groups in producing transitional kinetics. Two o-anisyl groups give one-proton kinetics.

In several of the examples in Table 1, we see the two factors of NN'-polarization acting independently. A single p-anisyl group, and a single p-acetaminophenyl group, give pure one-proton kinetics, because the substituents in these groups release electrons sufficiently strongly from that position (para) which is shown by the detailed theory of the polar transition state to be the most effective⁴. Two o-bromophenyl groups lead to transitional kinetics, and two o-iodophenyl groups to pure one-proton kinetics, because the substituents, increasingly in this order, reduce base strength by impairing charge solvation. In each of these complementary types of case, the second of the possible factors exerts either a weakly countervailing or an undecided effect.

Rearrangement Products

The now considerable area of agreement of the kinetic findings with the picture presented by polar transition state theory sufficiently increases our confidence in the theory to allow the question to be pursued of how widely its descriptions apply to the formation of the various types of products. The new studies of products formed in kinetically defined conditions provide evidence on the matter.

Table 2. products of conversions of hydrazobenzenes by perchloric acid in "60 per cent" aqueous dioxan

Substituents in Ph groups	Order in H+	4,4'- linked	2,4'- linked	2.N'- linked	N,4'- linked	Dispropor tionation

(The figures are percentages. Jacobson's signs are used, as before', for major, minor and trace products, when the data do not warrant a figure.)

- Identity was not confirmed by direct comparison.
- † Whether 2, N'- or N,2'-linked was not determined.
- I Noticeable only at acidities well above the kinetic range.

As to products of rearrangement, the chief new point relates to p-semidine formation. In 1964, this particular rearrangement was left out of the scope of the theory, because Hammick and Munro had reported in 1950 that azo-compounds, which on reduction with stannous chloride or zinc and acid, gave both o- and p-semidines on catalytic reduction in acetic acid gave o-semidines but no p-semidines. They concluded that p-semidines are not formed in homogeneous rearrangements of hydrazocompounds by acids, unless heavy-metal ions are present which are involved in some vital way in p-semidine formation. Shine and Stanley recently remarked that the recorded evidence for this conclusion is not satisfactory. Certainly the conclusion itself is not correct; for, as shown in Table 2, we have found three kinetically controlled acid rearrangements of 4-monosubstituted hydrazobenzenes, without heavy-metal ions, which produce substantial amounts of p-semidines. The examples, 4-methoxy-, 4-chloro- and 4-nitro-hydrazobenzene, between them embrace both the one-proton and two-proton mechanisms. So we would now allow the polar transition state theory to include p-semidine formation, as it is easily able to do. An N-to-4' polar bond about 3 Å long in the transition state would have plenty of strength and, as has been explained, direction is no problem.

The displacement of NN'-bond electrons here is towards the 4-substituted ring, as it is in diphenyline formation. In o-semidine formation, it is in the opposite direction. It can be seen from this that what we often shortly call "the" transition state might in reference to one product be represented by a simple energy col, but when several products are collectively considered is better represented by a group of cols, all within a few times kT of one another. This concept has been experimentally supported for the uncatalysed reaction^{3,4}. For the theoretical reason given, we adopt it for the acid conversions, though the obvious check of the temperature dependence of the isomer proportions has not yet been applied.

Disproportionation Kinetics

We know that disproportionation has both base-catalysed and acid-catalysed mechanisms, and that, through the latter, it accompanies many acid-catalysed rearrangements. We also know, and have confirmation in the present work, that, like the rearrangements, the accompanying disproportionations are kinetically of first order in hydrazo-compound. This is notable, because the stoichiometry of rearrangement involves only one hydrazo-molecule, but that of disproportionation involves two. The kinetics show that only one of the two can be concerned in the rate-controlling step. The second must enter into a subsequent fast step. There must, then, be an intermediate compound characteristic of disproportionation.

We now extend the kinetic description of disproportionation with respect to its dependence on hydrogen ions. In all the examples in the tables in which rearrangement and disproportionation occur in comparable amounts, the ratio in which the two groups of products were formed was found to be independent of the concentration of the catalysing hydrogen ions over the investigated range. This was true whether the overall conversions were of second or first order in hydrogen ions. Thus the kinetic dichotomy of rearrangement applies quite identically to disproportionation, the latter process taking its whole kinetic form from the rearrangement which it is accompanying. Table 2 contains, in the conversions of 4-methoxy- and 4-acetamino-hydrazobenzene, the first examples of one-proton disproportionation.

These kinetics show that the mechanism of disproportionation is grafted on to that of rearrangement at a late point in the reaction path, after the region of transition states has been passed over. At this point, an intermediate must be provided to engage with a second hydrazo-molecule in the second and fast step of disproportionation. The kinetics show that this intermediate must be formed at low enough energies to preclude any reversal of its formation. The second and fast step must comprise the redox process characteristic of disproportionation.

Disproportionation Products

The study of products has shown in three ways that the redox process occurs without preliminary fission of either of the two diaryl species involved. First, the oxidizing fragment of a preliminary fission would be a nitrene (in an equilibrium degree of protonation), and thus the benzene rings of the resulting azo-compound would come from different original hydrazo-molecules. Consistently with all older work, our study has shown that an unsymmetrical hydrazo-molecule AB gives only the unsymmetrical azo-molecule AB and not the symmetrical azo-molecules AA or BB.

Secondly, if a nitrene had any free existence, it would pick up fragments of solvent molecules, to produce, for example, amino-phenols from aqueous solvents. product of this nature has ever been found. We found none, despite the routine searching of residues by chromatographic methods.

Thirdly, we carried out the following experiments. A rapidly reacting and a slowly reacting hydrazo-compound are treated together with acid in such conditions that, if treated separately, the former would be converted completely and the latter not at all. Treated together, the latter becomes oxidized to its azo-compound, and the former accepts an equivalent amount of reduction to fission amines. Shine and Stanley recently recorded such an experiment, using 4,4'-diphenyl- and 4,4'-dichlorohydrazobenzene 5 ; and our results contain a second example, which employs p-acetamino-hydrazobenzene and hydrazobenzene. Cross-oxidations without crossed products are consistent only with electron transfer between unsplit diaryl molecules. Thus the intermediate of disproportionation must be an unsplit molecule.

When we consider the intermediates established for rearrangement, we find one family of intermediates which might meet the requirements of the intermediate of disproportionation. They are the quinonoid, ring-linked,

but still protonated intermediates (one of which is illustrated in the scheme below), which come first on the reaction paths after the transition states. We must assume that they, or some of them, can be split by reduction, to an exclusive extent if the atom or group R is such that its loss does not compete.

Decametric Radio Emission from Jupiter

Ьу O. B. SLEE* H. GENT Royal Radar Establishment, Malvern

Observations of the decametric radio emission from Jupiter establish the existence of a hitherto undetected sub-millisecond component. Bursts of between 0.2 and 10 msec are not due to interplanetary scintillation but come from the planet itself.

During the winter of 1965-66, observations of the decametric pulses from Jupiter were carried out at the Royal Radar Establishment, Malvern, using spaced receiving aerials. The purpose of the experiment was to find out whether the millisecond burst structure could, like the bursts of a few seconds duration, be the result of interplanetary scintillations^{1,2} imposed on a relatively slowly varying Jovian radio emission. The investigation was made by observing differences in time of arrival of bursts from Jupiter at three spaced aerials. If the burst structure were the result of the interplanetary medium moving at solar wind velocities, time differences in the range 1-10 msec would have been observed. The results show that the millisecond bursts are not imposed by the interplanetary medium, but are caused by variation of amplitude or frequency in the source itself. In addition, the existence of a hitherto undetected sub-millisecond component has been established; its presence during all intense Jovian emission strongly suggests that production of this component is a basic property of the emission mechanism.

The equipment consisted of three aerials placed at the corners of a right-angled triangle with sides 1.52, 1.27 and 0.85 km. Each aerial was made up of two horizontal half-wave dipoles, linearly polarized and phased to give maximum response in the direction of Jupiter at transit. The aerials were connected by low-loss feeders of approximately equal length to a central position, where they were applied in pairs to two similar receivers tuned to the same frequency in the range 19.7 to 20.2 Mc/s; the receiver bandwidths were 10 kc/s. The detected outputs were applied to the vertical deflexion plates of a double-

* Present address: CSIRO Division of Radiophysics, Sydney, Australia.

beam oscilloscope with the time-base length set to 20 msec. When intense Jovian emission was detected, the display was photographed on 35 mm film moving continuously in a direction perpendicular to the time bases at 20 cm/sec. As the Jupiter storm continued, the three aerials were applied cyclically in pairs to the two receivers, giving recordings on each of the three baselines. The magnitudes of the instrumental time delays were monitored by recording a sine-wave modulated signal from a common source at the beginning and end of each observing session. An auxiliary double channel pen recorder which ran continuously during times of expected Jovian emission was used to monitor the signals received by the aerials, and one of the receivers was also monitored aurally.

The baselines between the aerials used in the present observations were relatively short, and this made it necessary to resolve time differences of less than a millisecond between bursts received at different aerials (assuming the bursts to be due to interplanetary scintillations). The advantage of using short baselines is that the effects of the Earth's ionosphere will be reduced, because the correlation of the Jovian signals at the spaced aerials will be destroyed much less frequently than for long baselines. At the short separation the Faraday rotation at any aerial differs negligibly from that at any other, and the components of the ionospheric amplitude modulation pattern corresponding to spatial wavelengths around 1 km in the ground diffraction pattern are seldom strong enough to produce more than partial decorrelation of the signals.

During the Jupiter runs, some observations were made

of the 20 Mc/s continuous wave signal radiated by the S-66 satellite passing overhead at a height of 1,000 km.

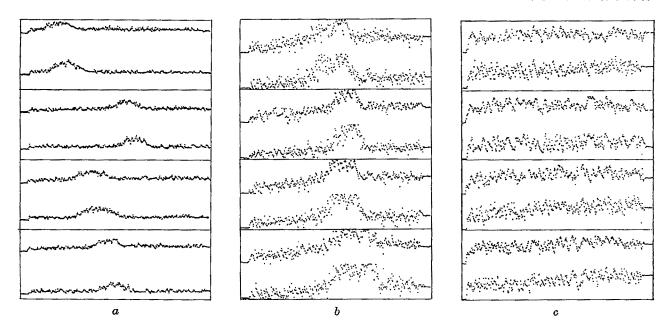

Fig. 1. Three examples of the 20 Mc/s radio emission from Jupiter recorded with spaced aerials connected to two receivers. The time-base lengths are 20 msec and time progresses from left to right and top to bottom. The traces are photographed in pairs, one receiver providing the vertical deflexion for each member. The original films have been digitized with 350 samples/time-base length. The receivers are suppressed during the short reference portions at the left of each trace. a, 4 mese pulses showing relative time shifts, north-south baseline, 1965 Jan. 23, 21h 83m ut. b, 5 msec pulses with much sub-millisecond structure, north-south baseline, 1965 Dec. 23, 00h 30m ut. c, Well developed sub-millisecond structure superimposed on a much slower 100 msec burst, south-east baseline, 1965 Dec. 8, 22h 34m ut.

Scintillations at frequencies corresponding to spatial wavelengths around 1 km on the ground never showed modulation depths of more than about 20 per cent, while frequencies corresponding to 5-10 km separation often showed 50-100 per cent depth of modulation.

On most nights after 20 h UT it was easy to find a band of about 100 kc/s width free of interference from terrestrial transmitters; the observing frequency usually used was about 20 Mc/s. Terrestrial interference could readily be identified (if present) by its aural characteristics, its narrow band and the general appearance of the chart record. Observations were made when Jupiter's hour angle was between \mp 02 h and when the longitude of the planet's central meridian and the position of the Jovian satellite Io were most favourable for the reception of decametric radiation³. During the interval November 1965 to February 1966 near opposition, strong Jovian emission was recorded photographically on twenty nights.

Some of the photographic records obtained during intense periods of Jovian emission were digitized by an electro-optical instrument of high resolving power for subsequent computer analysis; the sampling interval was 0.058 msec. An automatic graph plotter has been used to show some representative pulses from Jupiter in Fig. 1. Fig. 1a shows four consecutive pairs of traces, the two traces in each pair being triggered simultaneously. Pulses with durations of a few milliseconds are present, with a considerable amount of superimposed finer structure with durations as low as 0.2 msec. It is clear that the millisecond pulse envelope on the lower trace of each pair lags significantly behind the corresponding pulse on the upper trace. Similar time delays were recorded on all three baselines during this particular event. Fig. 1b shows four consecutive pairs of traces photographed on another night when the millisecond structure showed no significant time displacements: the sub-millisecond component is even more developed on these traces. In Fig. 1c we show four consecutive pairs of traces photographed on yet another night when a strong sub-millisecond component was superimposed on much slower variations with durations of about 100 milliseconds.

The average cross-correlation function between the pairs of traces of Fig. 1a is shown in Fig. 2a; Fig. 2b

and c are similarly related to Fig. 1b and c. The cross-correlations were calculated on the RREAC computer with a lag interval equal to the digitizing interval of 0.058 msec. Fig. 2a shows clearly that the millisecond pulses of Fig. 1a have suffered a relative shift of 0.38 msec between their arrival times at the two receivers. The small amplitude sub-millisecond component suffers no time lag, as is indicated by the presence of the small hump near 0 msec. In Fig. 2b, the more highly developed sub-millisecond structure shown in Fig. 1b is apparent: in this case neither the millisecond nor sub-millisecond pulses have suffered significant differences in arrival time. (The small difference of 0.029-0.058 msec apparent on the sub-millisecond structure in these cross-correlations is shown to be instrumental by the monitoring system.) Fig. 2c shows that the pronounced sub-millisecond pulses of Fig. 1c arrive together at the spaced aerials. In this case the average power spectrum of these pulses (computed from the Fourier transform of their autocorrelation function) shows that significant frequency components extend to about 6 kc/s.

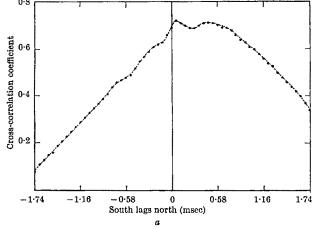

Amplitude variation with several different characteristic durations is present in the emissions. In Table 1 four categories of amplitude variation are listed, with the number of nights on which they occurred (out of the twenty active nights for which films were exposed). The table shows that the sub-millisecond structure was present during all periods of intense Jovian emission, although it is probable that the degree of modulation varied considerably. It is interesting that the sub-millisecond pulses appeared even when the bursts of intermediate length were absent.

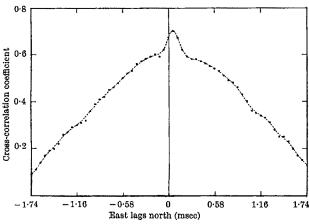

Table 1. TYPES OF STRUCTURE IN JOVIAN BURSTS

Component (msec duration) $0.1-1 \quad 1-10 \quad 10-100 > 100$ No. of nights present* $20 \quad 7 \quad 12 \quad 20$

* Photographic observations made on twenty active nights.

Because of the 20 msec length of time-base used throughout, bursts longer than about 10 msec cannot be subjected to digital analysis, and of the seven occurrences of 1–10 msec pulses only two were sufficiently prolonged to enable us to record the phenomenon on all three base

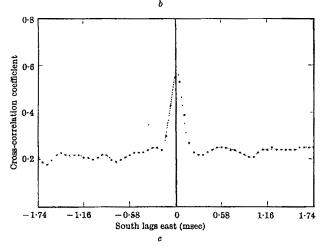

Fig. 2. Average cross-correlation coefficients between the members of the pairs of traces in Fig. 1. The lag interval is 0.058 msec and the total range 4.08 msec, giving an equivalent frequency resolution of 250 c/s. No corrections have been made for the non-zero means and slopes of the traces. a, b and c refer directly to the corresponding traces in Fig. 1.

lines. We discuss these cases (December 23, 1965, and January 23, 1966) in some detail.

The recorded millisecond pulses (see Fig. 1a and b) do not appear to possess the properties characteristic of irregular diffraction patterns drifting across the ground. Successive pulses are similar in shape and duration, tend to arrive at regular intervals of between 20-30 msec, and have widths of about 5 msec, giving a high interval to width ratio of about 6:1.

On the evening of January 23 the millisecond pulses showed consistent differences in arrival time at the receivers of about 0.5 msec for all three baselines: no

such differences were found on the records of December 23. On both occasions (as for nine other nights for which digitized results are available), the sub-millisecond structure did not suffer relative time shifts greater than 0.03 msec. The time delays measured on January 23 cannot be interpreted in terms of a drifting diffraction pattern across the spaced aerials because: (a) the delay was always present in the same receiver for all three combinations of pairs of aerials; (b) interchanging the aerial connexions to the receivers at a later stage of the same storm did not reverse the sense of the delay; and (c) the relative values of delay for the three baselines were not compatible with any velocity vector. Time delays with similar properties were measured during brief intervals of millisecond bursts on two other nights. On no occasion did we observe time differences which could be attributed to a velocity vector.

The time delays observed on January 23 are clearly associated with a difference between the two receivers used, a difference which did not appear when the instrumental time delays were monitored using a sine-wave modulated signal, from a single radio frequency source. The explanation is probably that the Jovian emission was drifting in frequency, and that there was a differential tuning error between the two receivers. Although the receivers were always tuned to within I ke/s of each other (tuning was checked at the beginning and end of each observation), delays of about 0.5 msec would result if a burst of Jovian emission drifted across the receiver pass bands at less than 2 Mc/s \sec^{-1} . The instantaneous bandwidth occupied by millisecond pulses has been shown by Riihamaa4 to be as low as 50 kc/s, the limiting frequency resolution of his radio spectrograph. Emissions of bandwidth between 10 kc/s and 50 kc/s drifting through the pass band of the receivers at rates of the order of 2 Mc/s sec-1 would produce millisecond pulses similar to those of Fig. 1a and b. Gordon and Warwick⁵ have observed bursts drifting at various rates, up to 35 Mc/s sec-1 for the bursts of largest rate. Such drifts are associated with fine structure in time: durations were less than 20 msec, the limiting time resolution of their equipment.

The sub-millisecond structure has shown no detectable time lag on any of our records. Such structure could be produced by emissions of less than 50 kc/s bandwidth drifting at rates of 20 Mc/s sec⁻¹ or by emissions without frequency drift modulated with sub-millisecond periodicities. The results of Gordon and Warwick⁵ show that both types of behaviour can occur when millisecond time structure is present; our results are consistent with similar behaviour for sub-millisecond time structure.

It seems unlikely that the sub-millisecond pulses could be caused by the sweeping across the Earth of a lobe pattern formed by coherent radio emission from large source regions on Jupiter, as suggested by Gordon and Warwick^{5,6} to account for the bursts of intermediate duration. Pulses of 0.2 msec duration imply a source region of 250,000 km in width, more than the diameter of the planet (140,000 km). Pulses formed by a sweeping lobe pattern should suffer arrival time differences of about 1 msec over distances of about 100 km in the direction of the velocity vector. An experiment aimed at detecting such a time difference would be worth performing.

The chief result of the present observations was that, for Jupiter bursts of duration between 0.2 and 10 mscc, time delays corresponding to solar wind velocities were not observed. Assuming that projected diffraction pattern velocities resulting from movements of the interplanetary medium are likely to lie in the range 100-1,000 km/sec, time delays between 10 and 1 msec should have been observed: the equipment used would have shown such delays very clearly. The millisecond and sub-millisecond bursts from Jupiter are hence not imposed by the interplanetary medium, and must originate from the planet itself. This conclusion is in agreement with the conclusions of Gordon and Warwick^{5,6} based on spectral observations. The

observed pulses may be the result of rapid variations in either amplitude or frequency or both. The evidence shows that some of the millisecond pulses are produced by frequency drift. The sub-millisecond structure is of relatively frequent occurrence, showing frequency components up to 6 kc/s. The absence of an interplanetary origin for pulses of less than 10 msec duration is consistent with recent observations of the spectra of interplanetary scintillations by Cohen et al., in which the power spectra were not found to extend much above 10 c/s.

Further investigations of Jupiter's decametric emission with higher time resolution are needed: it is also clear that studies of the frequency structure and drift rates are

required to elucidate the relative importance of time and frequency variations in producing the bursts of millisecond and shorter durations.

We thank Dr G. N. Taylor for assistance in observation and discussion

Fission Products of Unusual Composition in Finland

by

PENTTI KAURANEN

Department of Radiochemistry, University of Helsinki

ANTTI KULMALA ROLF MATTSSON

Finnish Meteorological Office, Helsinki

A cloud of fresh, highly fractionated fission products was observed in Finland between December 21 and 26, 1966. They seemed to come from Central Asia and were probably the product of an underground nuclear test.

In the morning of December 21, 1966, the radioactivity in the air unexpectedly rose in the eastern part of Finland. The front of active air moved westward at a speed of some 15 km/h and covered the whole country within 28 h (Fig. 1). The path of maximum ground level concentration, however, moved initially north-west, and later north-east at a speed of about 40 km/h.

Light snow with a specific β -activity of 1-3 nc./l. fell sparsely during this period. The β -activity, which was deposited through precipitation, amounted to about 10 nc./ m² in southern Finland and to about 2 nc./m² in northern Finland.

An autoradiograph of an air filter sample showed a very homogenous blackening of the film. No hot spots were detectable. Nearly all the previous samples in December had contained hot particles (originating apparently from the Chinese nuclear test of October 27) and so a new unknown source had to be considered.

The β -decay of an air filter sample (Whatman GF/A, glassfibre), collected at Nurmijärvi (see Fig. 1A) between December 22 at 15.30 GMT and December 23 at 08.00 GMT, was followed with a digital logger from December 24 to February 11 (ref. 1). Six 2.6 mg/cm² end-window counters took the measurements directly from the surface of the filter through different Al absorbers. Using the technique indicated in Fig. 2, we drew the following conclusions. The β -activity was chiefly a mixture of ⁸⁹Sr and ¹⁴⁰Ba- ¹⁴⁰La, with a ⁸⁹Sr/ ¹⁴⁰Ba activity ratio of 1.60 on December 24 at 00.00 gmr, and at least two additional β-emitters (half-value thickness ca. 10 mg/cm²) were present, with half-lives of about 3 days and between 20 and 40 days.

An air filter sample, collected at Nurmijärvi on December 22 between 06.00 and 13.30 GMT, was measured gamma spectrometrically several times between December 23, 1966 (Fig. 3), and April 1967 using a Ge(Li)-detector. The γ-peaks of the short lived fission products 140Ba-140La and 132Te-132I could be immediately identified in the γ-spectra (Table 1). A small peak at 365 keV indicated the presence of ¹³¹I, and a short lived peak at 280 keV remained unidentified. The half-lives given in Table 1 are

calculated from the successive γ-spectra, and the intensities are based on experimental efficiency curves and decay scheme data of the Nuclear Data Sheets².

A quarter of the same filter sample was leached with concentrated hydrochloric acid and I, Te, Zr, Ba and Ce carriers were added. The carriers were chemically separated and purified, and the y-activities were shown to follow the appropriate carrier. The 668 and 772 keV γ-peaks grew into the tellurium fraction, confirming that they were ¹³²I. No activity was observed in the zirconium fraction. This is in agreement with the absence of the

140Ba	450 ± 70	1.0
181]	< 40	< 0.15

* The *OSr values have not been corrected for the activity from old tests.

732 keV γ-line of ⁹⁵Zr in the gross γ-spectrum. No ²³⁹Np could be detected either. Peaks corresponding to the γ-energies of ¹⁴¹Ce, ¹⁰³Ru and ¹³⁷Cs were visible after the short lived activities had decayed. None of these peaks could be detected in a reference sample collected at Nurmijärvi on December 20, 2 days before the fresh debris arrived.

A sample of the top layer snow was also collected on December 24 in Helsinki, and ¹⁴⁰Ba, ⁸⁸Sr, ⁹⁰Sr and ¹³¹I were determined radiochemically. The results are given in Table 2.

The presence of an appreciable amount of ¹³²Te in the aerosol sample suggests that the debris had a rather short age. Calculation of age was based on the fact that ¹⁴⁰La

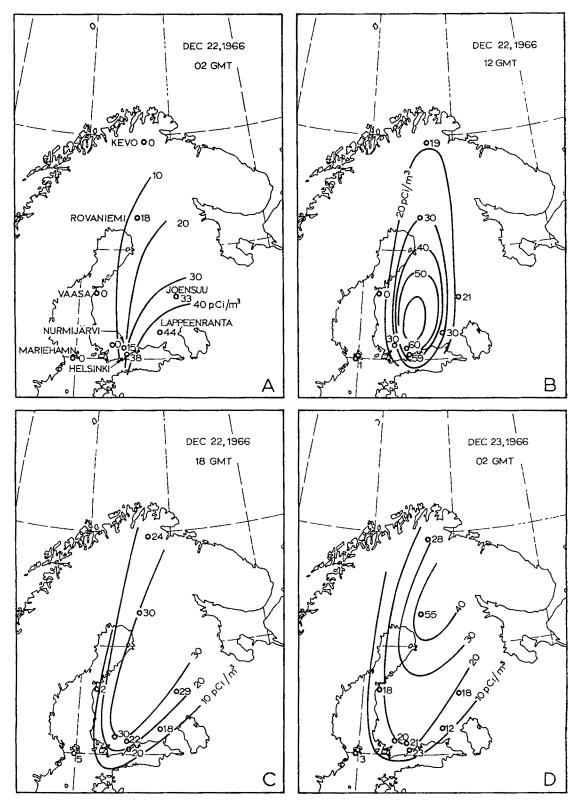

Fig. 1. Movement of the radioactive cloud over Finland during December 22.

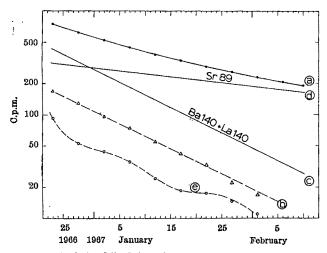

Fig. 2. Analysis of the beta emitters on the basis of decay curves measured through different absorbers. (a) Decay curve taken with a 2-6 mg/cm² end window counter. (b) Decay of an "excess" of soft betas, showing the half-life of ¹⁴⁰Ba. (Let the counting rate through an absorber of 100 mg/cm² be f and without an absorber a. The ratio alf approached 2-5 at the end of the measuring period. Curve b is obtained by plotting the expression a-2-5 f, (c) and (d) Main components of curve a. (e) A curve equivalent to curve b except that the absorber of 9 mg/cm² was employed. The influence of soft β -components of some 3 days and 30 days half-lives can be seen.

was not yet in equilibrium with 140 Ba in the first γ -spectra. An age of 5.5 ± 0.7 days, counted from December 23, 12.00 gMT, was obtained.

For investigation of the fractionation of fallout it is usual to use 95 Zr as a reference (compare refs. 3, 4 and 5). We did not find this nuclide in our samples and so have defined the fractionation factor f(A) in relation to 140 Ba.

$$f(A) = \left[\frac{N (A)}{N (^{140}\text{Ba})}\right]_{\text{exp}}^{\bullet} \left[\frac{N (^{140}\text{Ba})}{N (A)}\right]_{\text{theor}}$$

where N(A) is the amount of nuclide A at the time of production. The theoretical ratio refers to the fission yields of the thermal neutron fission of ²³⁵U. Our fractionation factors are given in Tables 1 and 2. The strongest enrichment is shown by ⁸⁹Sr and ¹³⁷Cs; these nuclides

also have rare gas precursors with the longest half-live (3·2 min and 3·9 min, respectively). Strontium-90 we apparently enriched to a lower degree (**0Kr has a half-liver of 33 see), while all the other nuclides observed were depleted in relation to **140Ba* (which has a 16 sec precursor **140Xe). Tellurium-132 has no gaseous precursor; howeve it is known that tellurium is relatively volatile at hig temperatures*.

It is interesting that fresh nuclear debris showing similar enrichment of the "volatile" fission chains we observed during January 1965 in Japan by Koyamet al.". They conclude that the activity originated in leak at an underground nuclear test near Semipalatins USSR.

Fig. 4 gives a good picture of the weather during th period; it shows an analysis of the mean isohypses a 850 mbar. The period covered is from 12.00 GMT o December 17 to 12.00 GMT on December 22. In Europea Russia and the western Asiatic Russia it was dominate by an area of high pressure, but there was a trough extending from Scandinavia to the Black Sea.

Surface winds were ageostrophic, and their direction in southern Finland was east and south-east. The difference between the surface winds and those at 850 mba first suggested that the radioactive air came with a fascurrent at the 850 mbar level to areas lying east and south-east of Finland. While travelling in this direction radioactive air subsided and was carried westwards by surface winds. Radioactivity at ground level first roswhen this air from the lower troposphere reached Joensus (Fig. 1A). Maximum beta activity was observed when radioactive air arrived with a surface wind on a longe route parallel with the radioactive flow in the troposphere.

Using this hypothesis, a CAV trajectory, calculated backwards from the White Sea, has been drawn in Fig. 4 Measured winds and 12 h steps were used. The time a the other end of the trajectory was 12.00 GMT on Decembe 18. There was a trough in the troposphere over the areast of the end point of the trajectory, and this led to divergence of flow patterns, and the calculation of the trajectory eastwards was not continued. Along the calculated trajectory the weather was extremely stable Many authors (for example, refs. 8 and 9) state that a centre

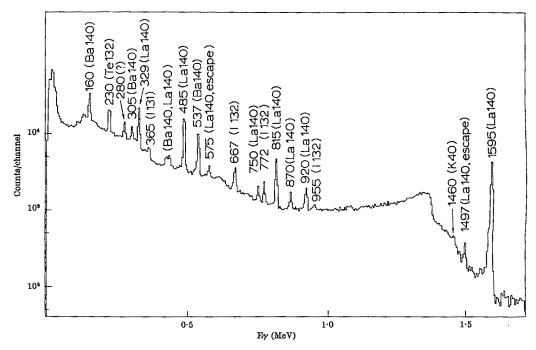

Fig. 3. Gamma spectrum of an air filter collected on December 22 at Nurmijärvi. The spectrum was measured by means of a 4 cm³ Ge(Li)-detector. Gamma-energies are given in keV.

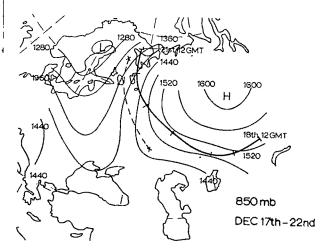

Fig. 4. 850 mbar mean contours for December 17-22. Heavy line is a CAV trajectory, calculated backwards from the White Sea. Broken line $(\times --- \times)$ is the cross section in Fig. 5.

of high pressure associated with stability in the troposphere is conducive to long-distance transportation.

Fig. 5 is a thermal cross section at 00.00 GMT on December 20, 1966. The cross section in this diagram lies along the line x - - x in Fig. 4. Fig. 5 shows that at 850 mbar there was relatively warm air (-10° C) with a layer of colder (-20° C) air under it. The troposphere from the inversion layer to ground level was sharply separated from the upper troposphere. In this case, a stable inversion at roughly 850 mbars made the preservation of high concentration possible.

The winds over Saratov and Moscow shown in Fig. 5 explain how the radioactive air moved so far in such a short time. Inversion wind maximum, first presented by Blackadar^{10,11}, increased at the stable inversion layer, and the maximum wind observed at 850 mbar was 55 knots.

The strong fractionation of the debris can be explained by assuming a sudden release of volatile (particularly rare-gas) fission products, such as would be expected from an underground nuclear detonation. Meteorological considerations strongly point to a central Asian origin. According to seismological information¹², an underground nuclear test was carried out in the Semipalatinsk area on December 18 at 04.58 gmt. In view of the air trajectories and the calculated age of the fission products, this event could be the source of the radioactivity reported here.

No health hazards were involved in the deposition of the activity in Finland¹³.

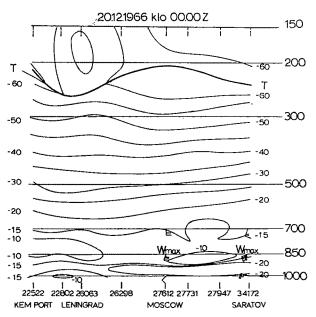

Fig. 5. Thermal cross section at 00.00 gMT on December 20, 1966. $W_{\rm max}$ refers to the lower troposphere.

We thank Professor J. K. Miettinen for his interest in this work, and Mr Henry Kalm for his help and for use of the Ge(Li)-detector of the Department of Physics for the first crucial γ-spectra. We also thank Miss Eira Akkanen for technical assistance.

Inorganic Pyrophosphate and ATP as Energy Donors in Chromatophores from Rhodospirillum rubrum

by
MARGARETA BALTSCHEFFSKY

Bioenergetics Group, Department of Plant Physiology, University of Stockholm Both inorganic pyrophosphate and ATP may function as biological energy donors in chromatophores from the photosynthetic bacterium. Rhodospirillum rubrum, causing energy requiring spectral changes in endogenous cytochrome(s) and carotenoid(s).

PHOTOPHOSPHORYLATION in chromatophores from the photosynthetic bacterium *Rhodospirillum rubrum* yields inorganic pyrophosphate (PPi) as the end product, in the absence of added adenine nucleotides¹. We have

reported earlier that these chromatophores contain an inorganic pyrophosphatase (PPase) which is usually more active than the corresponding ATPase, and that both these activities are stimulated by certain uncouplers

of oxidative phosphorylation and photophosphorylation^{2,3}. After these findings, we became interested in whether PPi, as an energy rich compound, could be used to drive energy requiring reactions in a manner similar to ATP.

ATP has long been known to serve as an energy source for pushing reactions of oxidative phosphorylation in animal mitochondria in the reversed direction, resulting in changes of the steady state oxidation levels of electron carriers4,5, including cytochromes8,7. In agreement with our working hypothesis, based on the similarities between PPi and ATP, we have obtained evidence, briefly reported elsewhere³, that not only ATP but also PPi can serve as an energy donor, causing an energy requiring spectral change at the level of endogenous cytochrome in chromatophores from R. rubrum. Results from further experiments with PPi as an energy donor in this system, and a discussion of the more detailed picture thus obtained about the energy transfer reactions involved, are given here.

The bacteria (Rhodospirillum rubrum Strain S1) were grown on a synthetic medium described by Bose et al.8 and the chromatophores were prepared according to the standard procedures of this laboratory. The "chromatophore fragments" fraction was secured and stored at 0°C after one washing in 0.2 molar glycylglycine, pH 7.4, in concentrated suspension. Concentration of preparations was measured at 800 m μ (OD_{800}). The energy requiring spectral changes were measured in a suitable dual wavelength spectrophotometer, after appropriate dilution with the buffer and addition of 3.3 mmolar magnesium chloride (final concentration). The Soret region of the spectrum was used for most of the experiments, because the strong absorption of carotenoids and bacteriochlorophyll rendered observation of specific changes of cytochromes at longer wavelengths extremely difficult.

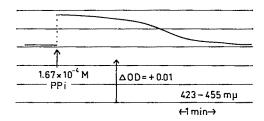

Fig. 1. Reduction of b-type cytochrome induced by addition of PPi. Reaction mixture contained in a final volume of 3 ml. : 0·2 molar glycyl-glycine buffer, pH 7·4, 3·3 mmolar magnesium chloride and chromatophores equivalent to $OD_{800} = 0\cdot900$.

A recording of a typical increase in absorbance induced by PPi at 423 mu is shown in Fig. 1. The change essentially represents the reduction of a b-type cytochrome. A return to the original level occurs when enough of the added PPi has been broken down by the strong PPase activity of the chromatophores. It will be shown here that the change induced by PPi is more rapid and greater than the corresponding change obtained with ĂTP.

As is shown in the difference spectrum given in Fig. 2A, the absorbance change obtained with PPi is greatest in the region 427-429 mu, which is the location of the Soret peak of the reduced form of b-type cytochrome in R. $rubrum^{10-12}$. It is further seen, in Fig. 2B, that PPi causes very distinct changes between 480 and 600 mµchanges which are known to be typical for carotenoids13. Similar changes were obtained when ATP was substituted for PPi.

Full extent of the cytochrome reduction can be obtained with as little as 6.7×10^{-5} molar PPi, as is shown in Fig. 3. The dashed line shows the trace obtained with 10-4 molar

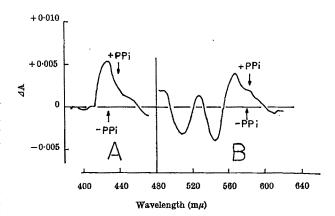

Fig. 2. Difference spectrum of changes induced by PPi in chromatophores. Both cuvettes contained in a final volume of 3 ml.: 0.2 molar glycyl-glycine buffer, pH 7.4, 3.3 mmolar magnesium chloride, 1.67 mmolar sodium succinate and chromatophores equivalent to $OD_{500} = 0.930$. 0.167 mmolar PPi (final concentration) was added to the measuring cuvette immediately before the spectrum was recorded.

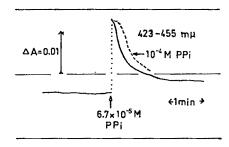

Fig. 3. Reduction of b-type cytochrome obtained by addition of low concentrations of PPi. Experimental conditions as in Fig. 1, except that the chromatophore concentration was equivalent to $OD_{800}=1.560$.

PPi in a subsequent control experiment, here superimposed for the sake of clarity.

Uncoupling agents such as gramicidin and desaspidin were found to inhibit the absorbance changes induced by both PPi and ATP. The inhibitory effect of gramicidin is shown in Fig. 4. In this system, the same low concentrations of gramicidin are needed as those required for interference with the photophosphorylation of ADP to ATP (ref. 14), or Pi to PPi (ref. 15).

If PPi is added after a maximum ATP-induced spectral change has been obtained and demonstrated by titration to excess ATP, there is always a further change, the total extent of which is the same as or greater than the change that can be obtained with PPi alone. In most preparations, also, addition of ATP to saturating concentrations of PPi gives some further change. These synergistic effects can be seen in Fig. 5. They appear to indicate that the ratelimiting steps of the reaction sequences between PPi or ATP and cytochrome are the reactions of these energy rich substrates with their respective enzymes, the reaction with ATP being the slower one. The reason why PPi gives both a more rapid and a more extensive reduction of cytochrome than ATP could be that PPi is more closely connected to the electron transport chain, so that fewer intermediate steps may be required to transfer the energy to the cytochrome level from PPi than from

Oligomycin is known not to inhibit the light induced formation of PPi (ref. 15), whereas the corresponding ATP formation is strongly inhibited by this compound¹⁴. In Fig. 6 it is seen that the reversed reactions behave in accordance with this, the cytochrome reduction induced by PPi being unaffected by oligomycin whereas the reduction induced by ATP is strongly inhibited.

It is now possible to construct a basic scheme including the metabolic connexion between PPi, ATP and electron transport, as well as the rate limiting steps in the "reversed" energy transfer from PPi and ATP to b-type cytochrome. $X \sim I$ is the hypothetical non-phosphory-lated, energy rich intermediate of the chemical theory for electron transport coupled phosphorylation. E_1 and E_2 indicate different enzymes (or possibly only different reaction sites on the same enzyme) mediating the initial reaction step from the respective energy donor towards the $X \sim I$ -level.

$$b$$
-type cytochrome \leftarrow b -type b -t

Keister et al. 16,17 have confirmed our first demonstration that PPi can function as an energy donor in chromatophores. They measured the energy-requiring pyridine nucleotide transhydrogenase reaction 18 and found that PPi, ATP or light could drive the reduction of added pyridine nucleotide. In their system also, oligomycin showed a strong inhibitory effect only on the ATP-driven reaction.

$423-455 \text{m}\mu$

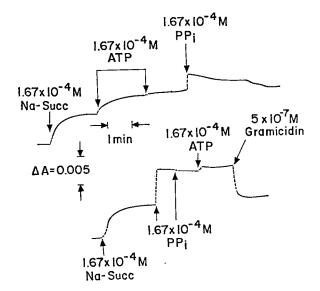

Fig. 5. The synergistic effects of PPI and ATP. Experimental conditions as in Fig. 1, except that 0-167 mmolar sodium succinate was included and that the chromatophore concentration was equivalent to $OD_{so} = 0.700$.

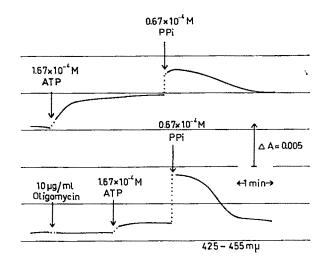

Fig. 6. Differential effect of oligomycin on PPI- and ATP-induced cytochrome reduction. Experimental conditions as in Fig. 5.

The assumption that the formation of PPi in photophosphorylation is of metabolic significance has been substantiated by the results, reported here, that not only ATP but also PPi can be used to drive energy requiring changes in the redox state of endogenous cytochrome. The ability of PPi to act as an energy donor in a pathway back to the level of endogenous electron transport is, however, not restricted to photosynthetic systems. We have now also been able to demonstrate PPi-induced energy requiring cytochrome changes in respiring mitochondria from both lower and higher organisms 19. In chromatophores, the unique response obtained has been that of endogenous carotenoid. Our finding that PPi and ATP change the absorption of carotenoid in the same direction as that which has been demonstrated earlier with light as energy donor¹³ indicates the existence of a metabolic connexion between light, PPi, ATP and carotenoid in bacterial photosynthesis.

I thank Dr Herrick Baltscheffsky for many valuable suggestions, and Professor Britton Chance and Dr Nils-Erik Saris for their help with the spectrophotometric experiments, which were performed in their laboratories.

Parabiotic Intoxication in Germ-free Mice

by LOUISE LEONARD

Microbiology Research Section, Veterans Administration Hospital, and Department of Pathology, University of New Mexico

ROBERT E. ANDERSON MARTIN L. OVITZ

Department of Pathology, University of New Mexico Germ-free parabionts show greater shifts in erythrocyte mass between partners than do conventional parabionts. The germ-free condition also permits longer survival of both partners. This raises important questions as to the role of bacteria and viruses in the pathogenesis of parabiosis intoxication.

Even after extensive investigation, the pathogenesis of parabiosis intoxication remains unknown. Billingham¹ has called attention to the similarity of this phenomenon to homologous disease and has suggested that similar mechanisms may be involved. Experiments with germfree animals implicate bacteria and bacterial antigens in many of the manifestations of runt disease². We have tried to define the role of bacteria and viruses in the pathogenesis of parabiotic intoxication.

Ten female germ-free mice, derived by Caesarean section at the Charles River Breeding Laboratories, were maintained in Trexler isolators and given free access to sterile fortified 'Wayne Lab Blox' and water. Ten additional germ-free mice of the same random bred strain were housed in standard animal quarters and freely fed unsterilized 'Wayne Lab Blox' and tap water. Mice were acclimated to these conditions for eight weeks before any experiment was carried out.

Five pairs of non-littermate germ-free mice, subjected to 'Nembutal' anaesthesia, were placed in parabiotic union of the coelomic type, as described by Martinez's, and maintained in the germ-free state for the duration of the experiment.

Mice were bled from the retro-orbital sinus before surgery and 3, 8, 12, 15 and 21 days after parabiosis. Haematocrits were determined and the sera then subjected to standard cellulose acetate electrophoresis and immuno-electrophoresis.

On the death of one parabiont the partner was killed and both animals autopsied. Organs were fixed in 10 per cent formalin and sectioned and stained with haematoxylin and eosin. At fortnightly intervals, faeces, food and bedding, removed from the isolator, were cultured in fluid media and smears examined microscopically.

Five pairs of conventional mice were parabiosed, bled and their organs treated as described here.

Erythrocyte shifts occurred in all pairs. As shown in Fig. 1, germ-free pairs manifested earlier and greater red blood cell shifts than their conventional counterparts. Significant anaemia—polycythaemia was apparent in all germ-free parabionts by the fifth day after anastomosis with the first change noted in two pairs on the third day; on the average, significant shifts were present in this group on the fourth day. The haematocrit of the polycythaemic partner in the germ-free group increased on average 26 units from a pre-operative average value of 57.6 per cent (range = 53–60 per cent) with a corresponding average fall of 30 units in the haematocrits of the anaemic partners. Corresponding values for the conventional pairs were as follows: first indication of anaemia—polycythaemia (one pair) on third day, all animals by twelfth day, average first appearance on ninth day; average increase in haematocrit of polycythaemic partner

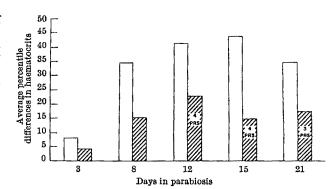

Fig. 1. Percentile haematocrit differences between individual parabionts in germ-free and conventional pairs as a function of time after anastomosis. White columns, germ-free parabiosis (5 pairs); hatched columns, conventional parabiosis (5 pairs).

12 units from a pre-anastomosis value of 47.5 per cent (range = 47-52 per cent); average decrease in haematocrit of anaemic partner was 18.0 units.

Additional haematological data for individual germ-free and conventional parabionts are summarized in Table 1, which also includes survival figures for each pair. Again it is apparent that maximum erythrocyte shifts were of greater magnitude in the germ-free than in the conventional group; germ-free parabionts became much more anaemic and polycythaemic than their conventional counterparts. Survival times, however, could not be predicted from the magnitude of the erythrocyte shifts.

Table 1. GERM-FREE VERSUS CONVENTIONAL PARABIONTS: SUMMARY OF HAEMATOLOGICAL AND SURVIVAL DATA

Pair	Lowest ha	ematocrit cent)	Highest ha		Survival (days)		
No.	Germ-free	Conven- tional	Germ-free	Conven- tional	Germ-free	Conven- tional	
$\frac{1}{2}$	6·8 24·5	14·8 32·5	80-0 80-0	60·0 79·5	34 22	15 27	
3 4 5	24·5 27·4 32·5	38·0 39·8 41·8	75·5 85·0 77·5	53·0 55·8 50·0	23 33 56	11 25 24	
Average	23-1	33-4	79•8	59•7	33-6	20-4	

Survival time in the germ-free parabionts averaged 33.6 days, with a range of 22 to 56 days and a median of 33 days; corresponding values for the conventional parabionts were as follows: an average survival of 20.4 days with a range of 11 to 27 days and a median of 24 days. In general, the anaemic partner died before the polycythaemic member in both the germ-free and conventional groups; however, in one germ-free combination, the polycythaemic member died first.

Gross autopsy examination revealed few differences. In both groups, the thymus of the anaemic member was

much smaller than that of the polycythaemic partner; the former was often difficult to identify while the latter seemed to be of normal size for the age of the mouse. Moderate splenomegaly occurred in all parabionts. The hearts of the polycythaemic mice were somewhat larger than normal while those of the anaemic animals seemed to be normal or slightly below normal in size. The large intestine of all germ-free mice was characteristically dilated. Displacement of portions of small and/or large intestine was present in four of five germ-free pairs and three of five conventional pairs; when present, such displacement always resulted in the presence of polycythaemic gastrointestinal tract in anaemic mice. In germ-free mice, such displacement, which included portions of the dilated large intestine, resulted in a distended, discoloured abdomen which was readily apparent before death. Germ-free pair No. 5, which survived for 56 days, did not show such displacement.

Microscopically, there were the expected differences between the lymphoid system of the germ-free and conventional mice. Spleens from germ-free mice contained only an extremely rare plasma cell, a paucity of large lymphocytes and in only one spleen were well developed germinal follieles evident. In contrast, conventional spleens contained numerous large lymphocytes which formed prominent germinal follieles; plasma cells were present in larger numbers than in the germ-free mice. Germ-free thymi contained few large thymocytes and lacked the numerous mitotic figures which were prominent in the conventional parabionts. Scattered nests of lymphocytes were found in assorted viscera of most conventional mice; these were not present in the germ-free parabionts.

There were few microscopic differences between conventional anaemic and polycythaemic partners. In general, the anaemic mouse died first and exhibited moderate autolysis while the polycythaemic member showed a modest degree of visceral congestion. In the germ-free group, comparable differences between partners were subtle but of interest. The polycythaemic partner appeared to have a greater number of large splenic lymphocytes than the anaemic member. Furthermore, survival appeared to be inversely proportional to the numbers of large lymphocytes contained in the spleen and thymus.

A comparison of the serum proteins in germ-free and conventional mice, as estimated by cellulose acetate electrophoresis and immunoelectrophoresis, revealed only the expected differences (Table 2); concentrations of serum gamma globulin and alpha-2 globulin were greater in conventional mice and concentrations of serum beta globulin were larger in the germ-free group.

Table 2. Germ-free versus conventional parabionts: summary of serum protein determinations*

	Germ-		
Serum protein	Anaemic	Polycythaemic	Conventiona
fraction	member	member	mice
Albumin	43.0	40·1	40-2
Alpha-1 globulin	11.3	10·0	10-0
Alpha-2 globulin	12.8	14·7	20-2
Beta globulin	31·3	26·4	19·6
Gamma globulin	0·4	5·4	8·7

^{*} Expressed as percentage of total proteins.

Serum gamma globulin concentrations in the germ-free group seemed roughly to correlate with survival, as shown in Table 3. Survival time was longest in those pairs (1 and 5) in which both mice showed markedly decreased or negligible gamma globulin. Furthermore, when there was a significant discrepancy between germ-free partners, the parabiont with more serum gamma globulin became polycythaemic with anaemia developing in the corresponding partner with the lower value (pair Nos. 2, 3, 4). There was no significant change in gamma globulin concentrations in any of the germ-free pairs during the course of the experiment with the possible

Table 3. RELATIONSHIP BETWEEN SURVIVAL AND PRE-ANASTOMOSIS GAMMA GLOBULIN DETERMINATIONS IN GERM-FREE PARABIONTS

	Serum gar	nma globulin*	
Pair No.	Anaemic member	Polycythaemic member	Survival (days)
1	0	3	34
2	0	10.6	22
3	0	8.35	23
4	2.2	7.9	33
5	0	0	56
Average	0.4	5·4	33-6

* Expressed as percentage of total proteins; comparable value for conventional mice = $8\cdot 7$ per cent.

exception of the polycythaemic member of pair No. 4; this animal exhibited a slight decrease on the fourteenth day after the operation.

Also in the germ-free group, there was a slight increase in concentrations of serum beta-2 globulin in all animals during the experiment. This change was slightly more pronounced in the anaemic parabionts. Serum protein determinations in conventional animals demonstrated no consistent differences between partners.

Much of the disagreement concerning parabiotic intoxication revolves around the putative role of immune mechanisms in the development and maintenance of the characteristic anaemia-polycythaemia. Hall and Hall's discount the importance of immunological factors in the pathogenesis of this phenomenon and suggest that the anaemia per se is responsible for the symptomatology of the affected partner. Others1,6 emphasize the similarities between the clinical expression of secondary disease and parabiotic intoxication in support of an immune actiology. Based on experiments involving F_1 hybrid mice joined to one of their parental strains, Hilgard et al.6 postulate that the anaemia-polycythaemia shift can be divided into two apparently independent phases. The experimental results of these investigators suggest that, although the initial erythrocyte exchange may be a reflexion of haemodynamic differences between the partners, the second phase is dependent on immunological differences between the parabionts.

This study reveals the following differences between germ-free and conventional parabionts of the same strain: the erythrocyte shift is much greater in the germ-free parabionts than in their conventional counterparts and the former pairs survive for a longer time post-anastomosis than do the conventional parabionts. The latter results may be unduly magnified by the presence of one germ-free pair which survived for an unusually long time (56 days); however, elimination of this pair still leaves an impressive survival differential (28-0 versus 20-4 days) favouring the germ-free group. It is tempting to attribute these differences directly to the absence of bacteria and viruses in the germ-free group. The present study, however, suggests that additional factors also may be operative.

Germ-free animals have poorly developed lymphoid systems, a paucity of immunocytes and low concentrations of serum gamma globulin. Their response to immunological stimuli and especially to tissue transplants⁷⁻⁹ is sluggish in comparison with conventional animals. If the second phase of parabiotic intoxication is on an immune basis, a reaction might be expected to be delayed or muted in germ-free animals. In this connexion, the prolonged survival of germ-free pair No. 5 is of interest; neither member of this combination had gamma globulin demonstrable by immunoelectrophoresis.

The association between prolonged survival and an increased erythrocyte shift in the germ-free parabionts was unexpected and is difficult to explain. A tardy response in the less sophisticated immune system of the germ-free animals might have modified release of vasoconstrictor substances and thus permitted the initial anaemia-polycythaemic response to continue for a prolonged period before restriction by the second (immune) phase of the reaction. Zweifach et al. 10 have shown that germ-free rats, after removal of blood, failed to rebound

to normotensive levels. A similar phenomenon might enlarge initial erythrocyte exchange caused by exaggerated blood pressure differentials between germ-free mouse parabionts.

Computer Simulation of Biological Pattern Generation Processes

by DAN COHEN Department of Botany, Hebrew University,

lerusalem

Simulation of the growth patterns of plants on computers provides a new approach to the study of some basic problems of morphogenesis.

SEVERAL lines of evidence suggest that the overall pattern of differentiation and morphogenesis in living organisms is produced by a hierarchically ordered set of interactions between genes, gene products and the external environ-

In this article, we report an attempt to simulate the growth of some biological patterns with the help of a digital computer, using the simplest possible generation rules and the smallest number of parameters in the programmes. Earlier attempts in this direction have been made2, and a preliminary report of this work has already been published3.

A Fortran programme, consisting of an organized set of generation rules, was written for each class of biological patterns to be simulated. Each set of rules has been derived from plausible hypotheses of the natural mechanisms. The rules were modified and extended as the work progressed to perfect the model.

For the sake of simplicity, our work deals only with branching patterns in two dimensions. This class of pattern is characteristic of vascularization in leaves and other flat or layered structures, and of branching on a flat surface. In fact, our simulation models are restricted to growth occurring at the free ends of branches, and to branching behind the growing tip.

The following are the generation rules for some classes of two-dimensional branching patterns.

Growth Rules

(i) Growth occurs only at the tips of branches.

(ii) The amount and angle of growth are determined by local density field, the direction and magnitude of the gradient of this field, the previous angle of the free end of the branch, and the tendency of the growing branch to persist in its original direction in spite of the gradient in density.

(iii) The density field around a point is computed by taking thirty-six sample points at intervals of 10° at a unit distance from the central point, and taking, as a measure of the density at each sample point, the sum of the squares of the reciprocals of the distances to all neighbouring parts of the pattern. The direction of the negative gradient and its magnitude are then computed by interpolation.

(iv) The extent of growth UG is given by

$$UG = U \cdot \frac{DGT - DMIN}{DGT} \tag{1}$$

where U is a unit distance, DMIN is the local minimum in the density field, and DGT is a limiting density above which no growth can occur. (Negative growth is not allowed.) The value of DGT determines the limiting

density of the pattern as a whole. (v) Growth angle GA is given by

$$GA = \frac{SA \cdot ST + GRA \cdot GR}{ST + GR} \tag{2}$$

where SA is the angle of the free end of the branch, ST is the inertial factor for growth direction, GRA is the direction of the negative gradient of the local density field and GR is the magnitude of the gradient.

A continuous iterative application of these growth rules leads to unlimited growth except when the minimum local density exceeds the limiting density for growth, that is, when DMIN > DGT. In general, the growth will be directed toward the unoccupied space outside the already existing pattern.

(vi) Growth may be directed by biasing the density field in any one direction in space.

Branching Rules

The branching rules, to a large extent, determine the final form and texture of the generated pattern.

(i) The density is computed for each potential branching point in the pattern in exactly the same way as for the growing points.

(ii) Branching probability PRB is computed according to the equation

$$PRB = \frac{DBT - DMIN}{DBT} \cdot \frac{DB - DBL}{DB} \cdot \frac{DD - DDL}{DD} \quad (3)$$

where DBT is the limiting density for branching, DB and DD are the distance from base and apex of the segment, respectively, and DBL and DDL are the respective limiting distances. DMIN has the same meaning as in the growth equation.

(iii) A random trial decides at each iteration whether branching will actually occur.

(iv) Branching angle BRA is determined in the same way as growth angle with the addition of a standard angle BRAS and a persistence factor, STBR. Thus

$$BRA = \frac{BRAS \cdot STBR + GRA \cdot GR}{STBR + GR}$$
 (4)

A continuous application of these branching rules, together with the undirectional growth rules (i)-(v), will generate uniformly spreading patterns which will assume an approximately circular shape, irrespective of the initial direction and asymmetry.

(v) Branching may also be directed by introducing a bias in the local density field. Growth bias and branching bias may be entirely independent, although they tend to reinforce each other if they are in the same direction. The whole pattern may thus be made to assume a directionality.

Both growth and branching rules may have their parameters changed as a function of some local or general property of the pattern. This introduces a hierarchical element into the generation process. Thus a specific branching sub-routine, applied only once at an early stage in the growth of the pattern, will determine the shape and relations of the primary branches. Alternatively, the parameters may be a function of distance from a local disturbance in the growth space, and this may result in specific "morphogenetic" effects. Also, branching may be completely inhibited in segments that have some particular spatial characteristics.

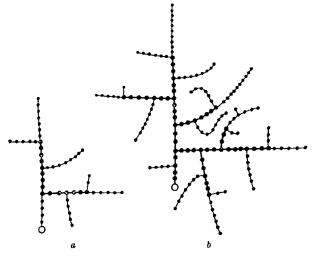

Fig. 1. Two stages in the growth of a simulated branching pattern. The persistence factors for growth and branching, ST and STBR, respectively, are both zero, so that both growth and branching always follow the negative gradient of the local density field. An intermediate spacing of the branches is caused by intermediate limiting distances between branching points, DBL for the distance from a basal branching point, and DDL for the distance from the distal end of the segment.

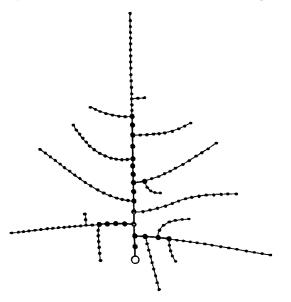

Fig. 2. This tree-like pattern is produced by increasing the limiting distance from the distal end of the segments, $DDL=10\cdot0$, while maintaining the limiting distance from the basal end at a low level, $DBL=1\cdot0$.

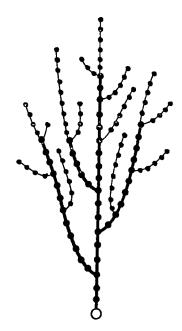

Fig. 3. A directed tree-like pattern is generated by blasing both growth and branching in the vertical direction.

We have introduced four principal effects:

(1) All the parameters for growth and branching may be different in branches of different ranks. This introduces an organization of branches into primary, secondary, etc.

(2) All the parameters may change their values during the growth process, depending on the total size of the pattern. As a measure of the total size, we have taken the total number of growth increments. This sequence of changes in the generation rules may result in marked differences between parts of the pattern formed at different stages of growth.

(3) The extent of growth and branching is made to depend on the distance from the basal and distal ends of each branch.

(4) Local disturbances in the growth space may increase or decrease growth and branching probability, and may do so to different extents in branches of different ranks. Branching may be directed towards or away from these local perturbations.

Some results of the simulations are shown in Figs. 1-6. In all the figures the starting point is represented by a circle. Those parts of the branching pattern which are no longer active in growth or in branching, that is, "old" segments, are represented by thick lines. The computed growth increments are indicated by the segments between the dots in Figs. 1-5.

In the simplest class of patterns there is no directional bias nor interaction with local disturbances. The growth and branching parameters remain the same in all parts of the pattern throughout growth (Figs. 1-2). The variety of patterns in this class depends on the distance between branching points, the standard angle of branching and its resistance to change by the local density gradient, and on the persistence of growth direction. This simple class is analogous to the growth of a mould in a uniform medium.

When a directional bias is introduced (Fig. 3), the effect is analogous to that of gravity on the growth of roots in a uniform medium, or to that of light on the growth of branching filamentous forms of algae and of moss protonema.

There are two types of hierarchical organization in our patterns, one according to the rank of the branches, and the other according to the total number of growth increments in the pattern. Both types may occur together. The first type of pattern takes the shape of certain kinds of tree. This is because the trunk, the major limbs, and

the secondary and tertiary branches all have their characteristic modes of growth and branching-a feature typical of many trees.

When the parameters vary as a function of the total size of the pattern, the modes of growth and branching differ in parts formed at different times during growth. This is analogous to the growth of moulds or trees when the external conditions change during growth, or when growth proceeds in a different way when the total size of the plant exceeds some critical value. This may be called a sequential morphogenes's (Fig. 4).

Patterns of a special kind result when a special branching sub-routine is applied only once early in the growth of the pattern. This sub-routine causes symmetrical branching, with equal angles between the branches, at the tip of the main branch when it reaches some critical length. The results simulate the venation pattern of maple leaves when five to seven branches are formed, or of clover leaves when there are only three branches (Fig. 5).

Patterns can be limited in extent, so that they resemble real plants more closely. This can be done by stipulating, for each rank, a minimum length beneath which branching cannot occur, and maximum lengths above which growth stops.

A most complex class of patterns resulted from the interaction of a growing pattern with local disturbances

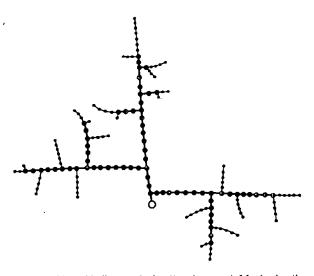

Fig. 4. A hierarchically organized pattern is generated by having the limiting distances for branching vary with the total number of points in the pattern. Both growth and branching are undirected.

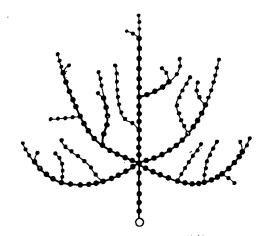

Fig. 5. This pattern is generated by the operation of a special branching rule once early in the generation process, arranged so that a number of branches are symmetrically spaced in relation to the primary axis. Growth is slightly biased upwards during some stages of the generation process, to give a leaf-like pattern.

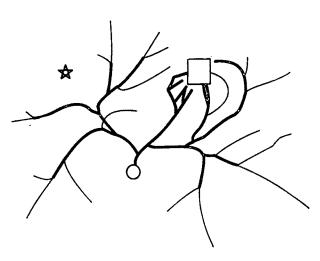

Fig. 8. This pattern is generated by the interaction of a growing pattern with a number of disturbances present in the growth space. Growth is directed towards attracting centres (squares) and away from repulsing centres (stars). The probability of branching increases near the attracting centres, and decreases near the repulsing centres. The growth of a branch which approaches an attracting centre closer than a critical distance is permanently terminated.

in the growth space (Fig. 6). These may be analogous to local sources of food in the growth of moulds, or to cell bodies of neurones which influence the growth and branching of other neurones. In this way, networks with functional characteristics can be produced.

A successful simulation of any one pattern is an analogue of the natural generation process. From such an analogue we can learn the following.

(1) The information content of a simulating computer programme is the upper limit of the minimal amount of information required to specify the simulated pattern. This limit can be expressed in binary bits, or in terms of the equivalent number of genes or the amount of DNA. The maximal information capacity of our programmes is $\sim 6\cdot 10^4$ bits, which corresponds to the DNA content of approximately 30 genes.

(2) The organized set of generation rules may be the most efficient language in which to describe and classify complex biological patterns. Any particular pattern in a class then corresponds to a particular set of values of the parameters in the generation programme for its class.

(3) Although the same pattern may be generated by several different simulation programmes, the characteristics of such programmes can suggest some general requirements for the natural generation process of any one class of pattern. For complex biological patterns, the simulating programmes may be useful in suggesting plausible mechanisms for the generation process. More definite conclusions can be reached about the minimal degree of complexity which is required in the generation of any class of pattern.

(4) A simulation programme which incorporates some hypotheses about the generation process of a natural pattern provides a method for an unambiguous rejection of incorrect hypotheses by comparing the natural pattern and its simulation.

ASTRONOMY

Friedman Cosmological Models with both Radiation and Matter

Jacobs1 has recently given an analytical solution of Einstein's field equations which represents a homogeneous and isotropic universe containing both radiation and dust; the space-like surface (on which the matter is comoving) is flat. Using arguments based on Mach's principle, however, Wheeler² argues that space is closed. This implies for a Friedman universe that the curvature is positive. But using statistical arguments and observational data, Chiu³ argues that the universe can be described by an open Friedman model with negative curvature. disagreement cannot be resolved at present because the energy density of the universe is not known to sufficient accuracy. Because of this, it seems reasonable to consider all three Friedman cosmological models.

A universe which is spatially homogeneous and isotropic but not necessarily flat can be described by the Robertson-Walker metric⁴

$$ds^2 = -dt^2 + a^2(t) \left[1 + (k/4)u^2 \right]^2$$

$$\left[du^2 + u^2 \left(d\theta^2 + \sin^2\theta d\varphi^2 \right) \right]$$
 (1)

where k=1, 0 or -1 correspond, respectively, to positive, zero and negative curvature of the space-like surface t = constant. We also assume that the radiation and dust expand independently and adiabatically and that $(8\pi/3)$ $\rho_m = K_m \ a^{-3}$ for the dust and $\rho_R = 3p_R = 3K_r a^{-4}/8\pi$ for the radiation, where K_m and K_r are constants. This choice satisfies the conservation law

$$T^{\mu\nu}$$
; $\mathbf{v} = 0 = (\rho a^3) \cdot + p(a^3) \cdot$

where the dot denotes differentiation with respect to time, ρ is the energy density, and p is the pressure. The only remaining equation to be solved is

$$\dot{a}^2 + k = K_m \ a^{-1} + K_r \ a^{-2}$$

If this equation and the conservation law are satisfied, the other Einstein equation is satisfied automatically.

The three solutions are

$$t - t_0 = (K_r + K_m a - a^2)^{\frac{1}{2}} + (K_m/2) \sin^{-1} \left[(K_m - 2a) (K^2_m + 4K_r)^{-\frac{1}{2}} \right]$$

for k=1 (positive curvature);

$$t-t_0=2 (K_m a-2K_r) (K_r+K_m a)^{\frac{1}{2}}/3K_m^2$$

for k=0 (zero curvature);

$$t - t_0 = (K_r + K_m a + a^2)^{\frac{1}{2}} - (K_m/2)$$

$$\log \left[(K_r + K_m a + a^2)^{\frac{1}{2}} + a + (K_m/2) \right]$$

for k = -1 (negative curvature).

The k=0 solution agrees with that of Jacobs¹, but for completeness I have given all three solutions. The requirement that a=0 at t=0 fixes the integration constant to

The Hubble constant $H = \dot{a}/a$ and the deceleration parameter $q=-\ddot{a}/aH^2$ are related to the total energy density and pressure through

$$3_q H^2 = 4\pi(\rho + 3_p)$$

Using the total energy density and the energy density of the radiation, one can (in principle) find the curvature constant k by means of

$$ka^{-2} = (8\pi/3) \rho - H^2$$

Because of the uncertainty in the density, however, there is no general agreement on the value of k (refs. 1-3). The situation is complicated still further because the mass density necessary for the binding of our cluster of galaxies is much larger than that observed.

Evidence for Lattice Bands in Interstellar Grains

THERE is considerable evidence from the infrared photometry of Johnson¹⁻³ that the wavelength range 3-10μ is associated with strong emission and absorption of radiation by interstellar grains. Several early type stars which exhibit excess infrared emission have been shown³ to possess extended circumstellar envelopes. It has been proposed by Stein⁴ that the thermal radiation from a size distribution of grains heated to about 300° K could explain this excess radiation. In such a model, which contains several arbitrary parameters, the precise location of the maximum emission at about 10µ must be regarded as rather fortuitous.

It has also been claimed that strong absorption amounting to ~1 mag occurs for some stars in the same wavelength range 3-10μ. To explain these observations, Johnson¹ has suggested that a bimodal size-distribution of grains may be present with peaks at radii of 3µ and 0.3μ . We then require that a sufficient density of grains of 3μ radius are present to give an extinction in the $3{-}10\mu$ waveband of about 1 mag over a typical distance scale of ~ 1 kparsec. If a is the radius, Q is the extinction efficiency and s is the density of a grain, the mass extinction coefficient is

$$\varkappa \approx Q \pi a^2 / \frac{4}{3} \pi a^3 s \approx 3Q/4as \tag{1}$$

With $Q \approx 0.3$, $a \approx 3 \times 10^{-4}$ cm and $s \approx 2.5$ g/cm³, we get $\kappa \approx 300$ cm²/g for the large grains at $\lambda \approx 10\mu$. In order to produce an extinction of about 1 mag we thus require a mass density of about 3×10^{-3} g/cm² projected on the sky. Over a distance of about 1 kparsec, the space density required is about 10-24 g/cm³. Although current estimates of the "hidden mass" in the galaxy correspond to a density of this general order, such a high density of heavy elements such as carbon and oxygen cannot be permitted. If the density of these elements were indeed comparable with the neutral hydrogen density, the composition of the surface layers of stars would be drastically different from what is observed. One must therefore look for an alternative explanation of the infrared observations.

We consider here the possibility that grains with impurity induced emission and absorption bands in the $3-10\mu$ waveband may account for the observed effects. Although it does not seem that grains in the general interstellar medium possess strong absorption bands at these wavelengths, the grains in localized HII regions may be considerably different in this respect. grains are exposed to a high flux of energetic particles which could produce lattice defects and consequent changes in their optical characteristics. The solid curve of Fig. 1 shows the infrared absorption spectrum of silicon crystals doped with lithium and boron impurities. The dashed curve is the absorption spectrum of silicon crystals irradiated with thermal neutrons7. In either case, there are strong absorption bands at frequencies close to

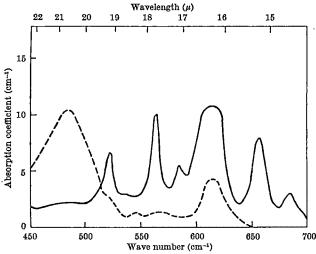

Fig. 1. The solid curve represents the infrared absorption spectrum of silicon crystals containing boron and lithium impurities in concentrations exceeding about 10¹² cm⁻³. The dashed curve is the absorption spectrum of silicon crystals at 77° K irradiated with about 10¹⁰ fast neutrons per cm².

about $k\Theta/h$, where Θ is the Debye temperature. For a typical absorption band the width is about 10 per cent of the central frequency and the oscillator strength is of order unity. A similar effect at about 3µ has been reported for quartz crystals with H-impurities8.

The vibrational spectra of pure crystals also possess peaks at frequencies close to about $k\Theta/h$. Pure quartz crystals show optically active lattice bands throughout the waveband 3-20 μ 9. In general, however, these modes are optically very weak in pure crystals, because the total linear electric moments tend to vanish owing to symmetry conditions. The presence of impurity atoms or defects destroys local symmetry and gives rise to optically active lattice modes. For irradiated graphite crystals, with $\theta \approx 1,000^{\circ}$ K, absorption bands similar to those in Fig. 1 may be expected to occur in a typical waveband 3-10µ. The possibility arises that such bands, in absorption or emission, may be picked up by Johnson's L, M and N

In the case of a star with an effective temperature of about 104 °K which is surrounded by a circumstellar shell, the total energy radiated in a 3µ wide waveband centred at about 10μ (appropriate for Johnson's N filter) is about 1031 ergs/sec. An excess flux of approximately 1 mag would result if the grains included in the field could radiate a comparable amount of energy over the same waveband. The radiating power of an excited impurity oscillator is about $8\pi^2e^2h/m\lambda^3$ ergs/sec, where λ is the wavelength and m is the mass of the oscillator. With $m \approx m_{\rm H}$ and $\lambda \approx 10\mu$, the radiating power is about 10^{-10} ergs/sec per oscillator, so an excess emission of about 1031 ergs/sec would result from approximately 1041 excited oscillators.

The focal plane diaphragm size used in Johnson's photometry is about 15". At the distance of the Trapezium stars this corresponds to a linear size of about 0.03 Johnson's infrared measures could therefore include the flux of an extended volume of about 1050 cm³, which may contain about 1039 grains. The observed excess emission would result if there are about 100 excited oscillators per grain.

Lattice bands occurring in absorption may account for the humps in the extinction curves at about 10µ reported by Johnson¹ for certain stars. The absorption cross-section of an atom near the centre of an atomic line of width y (in frequency units) is

$$\sigma_0 \approx \frac{4}{\gamma} \frac{\pi e^2}{mc} f \tag{2}$$

where f is the oscillator strength. For the usual case, where the line arises from an electronic transition, m is

the mass of an electron. In our case, the effective quantum oscillator is the entire atom so that m must be set equal to about $m_{\rm H}$. With $\gamma \approx 3 \times 10^{14} \, {\rm s}^{-1}$, and $f \approx 1$, we get from equation (2), $\sigma_0 \approx 2 \times 10^{-19}$ cm². In order to produce an extinction of ~1 mag/kparsec we require an oscillator density of about 10-3 cm-3. With a grain density of about 10⁻¹¹ cm⁻³ this corresponds to an impurity content of approximately 10⁸ atoms per grain, or about 1 per cent. It may not be unreasonable to find this high impurity content in grains in localized regions where severe particle irradiation may have taken place.

I gratefully acknowledge helpful discussions with Dr H. L. Johnson and Dr B. T. Lynds.

PLANETARY SCIENCE

Concentrations of Beryllium-7 over Australia during 1965

In an attempt to provide more information about the behaviour of the southern stratosphere, the fallout research programme conducted by CSIRO has been extended to include the measurement of beryllium-7, a radioisotope produced by cosmic rays, the atmospheric production rates of which have been thoroughly investigated1.

During 1965, a study was made of the tropospheric and stratospheric concentrations of beryllium-7 over eastern Australia. Air filters were exposed at altitudes between 5 and 30 km. Air samples from lower heights (5 to 20 km) were provided for analysis by the US Air Force which, at the time, was operating from Sale, Victoria, as part of the US Defense Atomic Support Agency's Project Stardust. Air samples from greater heights were obtained by carrying an air filtration unit as extra payload on the balloon flights conducted by the Australian Department of Supply at Mildura, Victoria, for the US Atomic Energy Commission ("Project Hibal").

Analysis was by gamma-ray spectrometry after the digestion of the air filters in nitric acid and precipitation of beryllium as the hydroxide. A 2 in. × 2 in. NaI(Tl) well crystal and a Philips single channel analyser were used.

In the case of the Hibal measurements, air volumes were measured by a calibrated flowmeter. Flow rates through the aircraft filter systems were calculated from the reported air speed and density using calibrations provided by Mr G. E. Stout of the Illinois State Water Survey (private communication).

Fifty measurements were made between June and November 1965. Fig. 1 shows the results obtained. Most of the aircraft samples were obtained near Tasmania, while the rest were taken during flights north of Victoria. Accordingly, two sets of aircraft data are shown, corresponding to the mean latitudes 42° S. and 25° S. All the balloon flights were conducted from Mildura (34° S.).

The curves shown in Fig. 1 are the equilibrium steady state concentrations calculated from the production rate model of Lal, Malhotra and Peters, who gave production rates as functions of the geomagnetic latitude. average geomagnetic latitude around a parallel of latitude is, however, numerically the same as the geographic

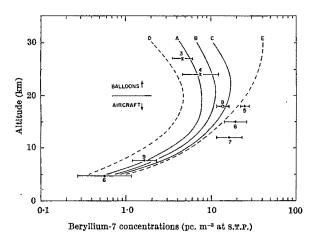

Fig. 1. Measured concentrations of beryllium-7 over eastern Australia at latitudes of 25° S. (○), 34° S. (×) and 42° S. (●) compared with the predicted equilibrium concentrations at the same latitudes (curves A, B and C respectively; see text). The number of measurements contributing to each point is shown, as is the logarithmic standard deviation. Curves D and E give the expected equilibrium concentrations at the equator and at 75° S., respectively.

latitude. Consequently, in the present calculations, the production rates have been weighted according to the range of geomagnetic latitude encountered during an assumed zonal flow.

In the derivation of the steady state concentration profiles of Fig. 1, no effects of mean motion or mixing were considered. Profiles north and south of the sampling latitudes are included for comparison. Errors in the estimated concentrations could be as great as 25 per cent.

The most striking feature of Fig. 1 is the large discrepancy between the measured concentrations of beryllium-7 between 10 and 20 km and the predicted equilibrium values. The four means plotted are about twice the values expected. The tropospheric measurements made using the same aircraft and sampling techniques and employing identical analysing procedures, however, agree well with the predictions of the model. It is therefore unlikely that the large concentrations at about 15 km are caused by errors of measurement alone.

An obvious explanation lies in the earlier disregard of stratospheric transport. Either of two processes, mean motion or mixing, can be invoked to explain the observations. Assuming a mean motion model, subsidence from greater heights and a drift towards the equator would be necessary. Studies of other tracers, however, suggest that if such a horizontal drift exists, its direction is towards the poles.

On the basis of a diffusion model, the large concentrations of beryllium-7 seen in the lower stratosphere can only be explained by stronger mixing poleward of 42° S. From stratospheric heat flux data of the northern hemisphere, Reed and German² derived values of the horizontal and vertical diffusion coefficients in 10° latitude steps. During the appropriate period (January to June in the northern hemisphere) and above 100 mbar, the average diffusion coefficients poleward of 40° were approximately three times those at lower latitudes. The aircraft measurements shown in Fig. 1 can be explained in these terms. The paucity of data and the experimental errors involved, however, make a lengthy discussion unwarrantable at this stage.

On the other hand, the average concentrations of beryllium-7 observed between 20 and 30 km were lower than the steady state equilibrium predictions. Because of the small volumes sampled, the total amounts of beryllium on 'Hibal' filters were small and the errors of measurement correspondingly large. It is possible that the filter material employed was not efficient for the low particle sizes known to predominate at about 30 km. Thus the obvious explanation that the small values observed imply

stronger mixing at lower latitudes should be considered with caution.

Other workers studying cosmic ray spallation products in the lower stratosphere have generally reported concentrations lower than the predicted equilibrium values. Drevinsky et al. measured beryllium-7 at about 35° N. during 1961 and 1962. Before the resumption of atomic weapons testing in October 1961, a mean beryllium-7 concentration of about 9 pc. m⁻³ at s.t.p. was obtained. This low concentration was explained in terms of the short residence time of the polar stratosphere.

Over southern Australia, low concentrations of beryllium-7 were found⁴, and these were attributed to either errors of measurement, errors in the production rate (of the order 25 per cent) or to mixing with the troposphere. Although the accuracy of the measurements now reported may be low, a systematic error of the order 100 per cent would be necessary to explain the results on this basis alone.

Determinations of beryllium-7 at between 20 and 30 km are continuing and attempts are being made to improve the accuracy of measurement. It is intended to expand the programme to include other cosmic-ray spallation products.

We thank Dr A. J. Dyer, Mr E. Curwood, Mr G. E. Stout and the personnel of the Fifty-eighth Weather Reconnaissance Squadron for their help. Mr G. Grauze performed the beryllium analyses.

Thickness of Etnean Lavas

WALKER¹ has reported observations made on the volcano Etna of the thickness of solid lava flows and the inclination of the slopes on which they lie. He also made estimates of the viscosity of the lava flowing down the slopes of Etna in May 1966, by measuring the thickness and velocity of flow of the lava and the angle of inclination of the slope. The formulae used to determine the viscosity are those for a Newtonian fluid exhibiting laminar flow. Walker sought a relation between the viscosity of fluid lava, the thickness of solid lava and the inclination of the slopes on which the solid lava lies. It seems, however, that such a relation is unlikely because a lava flow having the properties of a Newtonian fluid would continue to flow until no lava at all remained on the sloping surface. Hot lava is observed to flow and cold lava is found to rest on sloping surfaces, however, so we may surmise that flowing lava is not Newtonian in its behaviour, at least as it approaches a fully solid state. Walker's valuable observations enable these questions to be investigated. If the thickness of solid lava flows were determined by the viscosity of the lava when liquid, if this had the properties of a Newtonian fluid, and if the flow were laminar, we should expect to observe a relation between angle of slope, α , and solid thickness, h, of the form

$$h^2 \sin \alpha = K$$

where K is a constant. In practice, Walker's observations do not support a relationship of this form but, rather, one of the form

$$(h_v \max) \sin \alpha = k$$

	Tab	le 1	•
(h max) (metres)	(degrees)	h, max	(h _v max) sin α
20.0	3.9	20.0	13.6
15.0	5.0	15·0	13·1
10.0	7.5	10.1	13.2
5.0	14.0	5.2	12.5
2.5	25.0	9.7	11.6

Values of (h max) and a have been taken from the upper dashed curve of Fig. 1 in Walker¹; $(h_{\tau} \text{ max})$ is taken to be $(h \text{ max})/\cos a$.

where $(h_v \max)$ is the maximum vertical thickness of lava found on any slope (see Table 1). Now $h_v \sin \alpha$ is proportional to the shear at the base of the flow caused by the weight of the overlying lava. That $(h_{\nu} \text{ max}) \sin \alpha$ should be constant for the solid lava flows on Etna suggests that in the final stages of solidification, as the final thickness is determined, the lava is non-Newtonian and approximates in its behaviour to a Bingham plastic2. If the stress acting on a Bingham plastic is smaller than a critical value, which is called the yield stress, no flow occurs, but if the stress acting on it exceeds this value then flow does occur. In the case of lava we may suppose that, as solidification occurs, flow continues until the thickness reaches a value such that, for the slope in question, the shear at the base of the lava caused by the weight of the overlying material becomes smaller than the yield stress, and that at this point flow ceases. If lava flows in the final stages of solidification do behave as Bingham plastics, it is clear that no lower limit to the thickness of a flow is set by this property and so flows may be of any thickness up to the limit set by the yield stress characteristic of the lava concerned and the inclination of the slope on which the lava lies. Walker's observations are consistent with these conclusions if the yield stress of Etnean lava in the final stages of solidification is about 2.5×10^6 dynes/cm². It follows that, in general, in the case of lavas tilted after their solidification, it is only the maximum thickness of lava at any locality which may supply information about the original slope.

I thank Mr C. A. W. Deane for drawing my attention to the properties of Bingham plastics.

Origin of Round-body Structures in the Orgueil Meteorite

MICROBIOLOGICAL examinations of carbonaceous meteorites have been conducted by Oro and Tornabene¹. They discovered bacterial contamination on two carbonaceous chondrites but were unable to detect bacterial affinity for a third meteorite—the Orgueil. We therefore have chosen to examine the Orgueil meteorite2 because of this reported lack of bacterial contamination. Reports of biological materials and life-like objects associated with the Orgueil meteorite, as presented by Nagy and Claus and their co-workers^{3,4}, have, however, aroused speculation as to whether they could be indigenous. cautious, one can always entertain the possibility of terrestrial contamination or artefacts created during treatment of the meteorite. Because there is ample evidence for biogenic substances existing in the Orgueil meteorite⁵, evaluation of their origin would seem to be the next step to take. To investigate the problem of contamination, we have attempted ultra-thin sectioning of mineral pieces

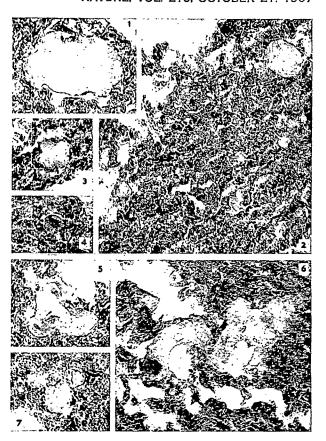

Fig. 1-7. Electron micrographs of ultra-thin sections of the Orgueil meteorite showing the round structures.

of the Orgueil meteorite. Nagy has advised us that any biological-like structures firmly embedded in the mineral matrix of the meteorite obviously could not be caused by contamination.

Small pieces of the Orgueil meteorite (from the Smithsonian Institution, Washington, DC, by courtesy of Dr G. Claus, Long Island University) were embedded in 'Epon' resin to facilitate sectioning. Being very hard, the meteorite specimens were sectioned with a diamond knife on an LKB microtome. The ultra-thin sections were then examined under a RCA EMU-3G electron microscope at 100 kV.

Electron micrographs of ultra-thin cross sections of the Orgueil meteorite reveal that the interior proper of the meteorite consists principally of ridges irregularly fitted together. These ridges are electron dense and are obviously the mineral materials. These mineral materials, although fitted together in one piece, are not structurally continuous—they are interspersed with gaps or fissures. The smaller holes are probably simply air pores. Among this vast area of mineral matrix, however, numerous objects or round structures can be readily observed. Contrary to the mineral materials, these round bodies are electron opaque. The surface, as well as the interior matrix of these round bodies, is continuous (Figs. 1-7). In addition, the surface of some of these round structures seems to be firmly and intimately enclosed by a thin layer of dark wall with an approximate thickness of 200 Å (Fig. 1). This enclosure might be contributed by the surrounding meteorite mineral matrix or might be an integral part of the round structure itself. The size of these objects is not uniform. They have various diameters of $1/8\mu$, $1/4\mu$, $1/2\mu$ and 1μ (Figs. 1-7). Most of them are round and single, but sometimes they appear together in close proximity to each other (Fig. 2) and are irregular in shape (Figs. 5 and 6).

The size, shape, electron density, interior matrix continuity, well defined surface contour and the thickness of the surface wall suggest that these round structures (bodies) possess some degree of organization (structural pattern). The mere fact that these structural bodies are located within the matrix of the meteorite mineral would render them relatively out of reach of factors which might produce artefacts or external contaminations. We are not suggesting that these organized structures are strictly biological bodies but we do wish to point out that they are very likely to be indigenous to the meteorite itself.

Late Pliocene-Pleistocene Stratigraphy in Deep Sea Cores from the South-central North Atlantic

PALAEOMAGNETIC studies of deep sea cores have shown that the history of geomagnetic polarity reversal is recorded in sea floor sediments¹⁻⁸. The local extinction of certain species of Radiolaria can be related to palaeomagnetic polarity reversals1,4,8, and specifically there is an association of the Brunhes-Matuyama polarity reversal at 0.7×10^6 yr ago with the ψ/X radiolaria faunal boundary4,8. Another such extinction has been suggested^{4,9}; the Φ/X radiolaria boundary, occurring within the Olduvai Normal polarity event about 2×10^6 yr ago. approximates the Plio/Pleistocene chronostratigraphic boundary defined by Ericson^{10,11} for oceanic sediments. Although this chronostratigraphic age assignment may be correct, the relationship of the geomagnetic polarity time scale to the biostratigraphic units used to define Plio/Pleistocene geological history has not been demon-This results primarily from the lack of appropriate palaeontological criteria in deep sea cores which can be correlated with the standard (type) sections of the Pliocene/Pleistocene of Italy.

In this report we make a preliminary attempt to relate the "absolute" geomagnetic time scale to Late Pliocene! Pleistocene geological history on the basis of new palaeomagnetic and palaeontological evidence in three deep sea cores from the central North Atlantic. A more complete discussion of our investigation of these cores has been given elsewhere2; here we give a brief account of our results.

The cores contain a distinct planktonic foraminiferal fauna, elements of which are found in the type marine Plio/Pleistocene sediments of Calabria, Italy¹². Specifically, Banner and Blow12 in their biostratigraphic zonation of the Neogene have drawn the base of the Pleistocene at the base of their zone N22. This zone is defined on the first evolutionary appearance of Globorotalia truncatulinoides from its immediate ancestor G. tosaensis. This transition was observed to occur near the base of the holostratotype Calabria at Santa Maria di Catanzaro, Italy. The utility of this zonation was demonstrated¹³ in a study of deep sea cores from the tropical Indo-Pacific Ocean. The Calabrian stage has been shown to be older than the earliest Pleistocene continental glaciations and an age of 1.8 × 10° yr has been estimated for the Pliocene/ Pleistocene boundary.

Preliminary measurements of the natural remancut magnetization (NRM) in eight piston cores obtained during Chain Cruise 61 across the Mid-Atlantic Ridge were made with an astatic fluxgate gradient magnetometer15. Three of the plastic tube-lined cores (Chain 61 (171). (174) and (175)) showed reversals of remanent magnetization. These core tubes were split open and small oriented cylindrical samples were extruded into polyethylene

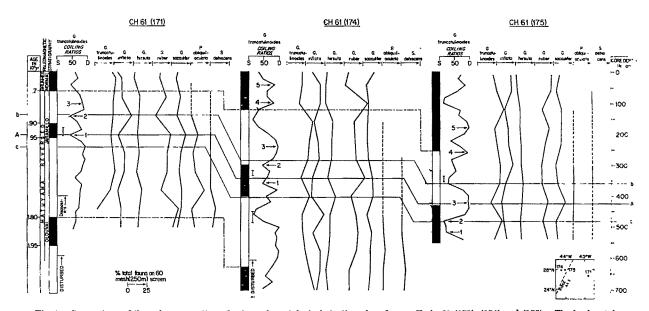

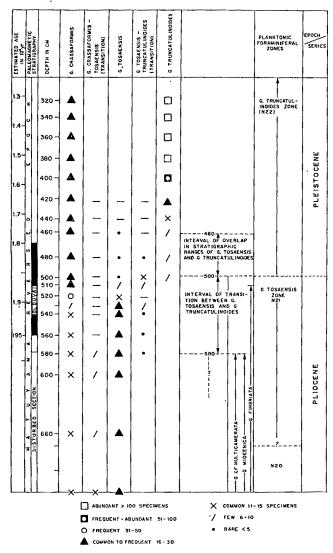

Fig. 1. Comparison of the palaeomagnetic and micropalaeontological stratigraphy of cores Chain 61 (171), (174) and (175). The horizontal lines show suggested levels of correlation among the cores based on distinctive fluctuations in the coiling ratio abundance of *G. truncatulinoides* and the relative abundance of the indicated foraminiferal species. The numbers are believed to mark points of general correlation in the coiling ratio curves for each core. The vertical bars adjacent to the magnetic stratigraphy column for each core delineate narrow bands of light grey brown foraminiferal lutite in the otherwise homogeneous pale brown foraminiferal lutite. The sketch map shows the location of the cores.

Relative abundance of Globorotalia truncatulinoides and Globorotalia tosaensis in the Chain 61 (171) core.

canisters and encapsulated with epoxy resin to form a rigid 5 c.c. sample. The NRM was measured again with a high frequency spinner magnetometer¹⁶.

The stability of each normal and reversely magnetized section along the cores was tested by partially demagnetizing representative specimens from each section in alternating magnetic fields¹⁷. The palaeomagnetic stratigraphy of the three cores after demagnetization at 150 oersted is shown in Fig. 1, together with curves showing the coiling ratio abundance of Globorotalia truncatulinoides and the relative abundances of certain foraminiferal species. All three cores appear to have penetrated the Jaramillo normal magnetic event at about 0.9 × 10° yr, the Chain 61 (171) core reaching the reversed interval below the Olduvai normal magnetic event about 2.0×10^6 yr ago.

In the Chain 61 (171) core, the transition from G. tosaensis to G. truncatulinoides was found to range from 580 to 500 cm and to occur within the Olduvai Normal event (Fig. 2). The first evolutionary appearance of G. truncatulinoides is at 500 cm, about 30 cm below the top of the Olduvai. Using the Pitman and Heirtzler¹⁸ time scale for palaeomagnetic stratigraphy, an age of 1.85×10^{6} yr is suggested for the base of the Pleistocene.

Globorotalia truncatulinoides develops from being a relatively rare form in Chain 61 (171) core at 500 cm to a dominant position in the microfauna above 400 cm.

This level was found to coincide approximately with the first disappearance of abundant discoasters in this core (between 420-400 cm); a brief reappearance of discoasters was found at 162-164 cm, within the upper part of the Jaramillo event.

The first appearance of Globorotalia inflata, a temperate water species, was found to coincide with the first evolutionary appearance of G. truncatulinoides. Globorotalia inflata has its maximum absolute abundance north of 40° N. latitude in the North Atlantic and maximum relative abundance approximately between 40° and 50° N. latitude.

The sudden appearance of G. inflata at 500 cm is interpreted to indicate a general decrease in the surface temperature of the sea. This climatic deteriorationmild though it probably was—may correspond to that recorded at the base of the Pleistocene at Le Castella, Calabria, in southern Italy¹⁹.

A comparative study was made of the three cores (Chain 61 (171), (174) and (175)) in an attempt to relate faunal changes to palaeomagnetic stratigraphy. results of our observations can be summarized as follows. (1) Although a normal magnetic event was recorded in the lower part of the Chain 61 (174) core, the planktonic foraminiferal fauna was wholly of Pleistocene character; the abundance of G. truncatulinoides and the absence of discoasters suggested correlation of the bottom of Chain 61 (174) core with a level above 400 cm in Chain 61 (171) core. Visual examination of the lower part of the Chain 61 (174) core suggests that vertical disturbance may be The resolution of this apparent conflict is left open at present. (2) A distinct inverse relationship was noted at a level within the Jaramillo event between the abundance of temperate species Globorotalia inflata, G. hirsuta and G. truncatulinoides on the one hand, and warm water Globigerinoides ruber, G. sacculifer and, in the case of the Chain 61 (171) core, Pulleniatina obliquiloculata. The marked increase in the former group is suggestive of a significant cooling at this level. The relatively common occurrence of G. inflata above the Jaramillo in all three cores is interpreted as indicating a continued important cooling trend within the Upper Pleistocene. In the light of recent evidence that the four "classic' glaciations of the Pleistocene may well have been preceded by one or more earlier glaciations, we suggest that this cooling event within the Jaramillo may indicate the onset of Pleistocene continental glaciation, or, at least, a marked cooling trend before the initial stage of glacia-

We thank Mr F. Jones and Mrs J. Brown, who made the measurements, Miss J. Golden for her help in the micropalaeontological analysis, the officers and crew aboard R.V. Chain for their co-operation and R. P. Von Herzen for helpful criticism.

This study was supported by the US Office of Naval Research, and the US National Science Foundation provided the fluxgate gradient magnetometer system.
